Each platelet contains approximately one fifteenth to one fifth the amount of antigen found on leukocytes.<sup>257,264,268</sup> A dosage effect has been shown for at least one antigen; the platelets of homozygous HL-A2 family members carry approximately twice as much antigen as do the platelets from heterozygous individuals.<sup>264</sup> It has also been shown that the amount of HL-A2 antigen present on the platelets of unrelated HL-A2 subjects is influenced by other genetic determinants belonging to the LA (First) series, but not by those belonging to the Four (Second) series.<sup>269</sup>

### Other Isoantigens Shared by Platelets and Leukocytes

In addition to the HL-A antigens, platelets and leukocytes also share the 5a/5b antigens, a presumably diallelic system first described by van Leeuwen.<sup>242,260</sup> The 5a/5b characters segregate independently of the HL-A system.

<sup>a</sup>Van Rood nomenclature

†Dausset nomenclature

Their presence on platelets is only detectable by absorption studies, a rather indirect technique.<sup>211,212</sup> The 9a antigen as well as the Na1, NB1, and Vaz antigens apparently are only found on leukocytes<sup>260</sup> (page 506).

### ABO Antigens

A and B antigens have been demonstrated on the surface of platelets by a variety of techniques<sup>269</sup> including adsorption experiments,<sup>253-277</sup> agglutination<sup>231,213,215</sup> and mixed cell agglutination studies,<sup>220-243</sup> complement fixation,<sup>209</sup> and platelet survival studies.<sup>210-238</sup> Whether A and B antigens are actually intrinsic parts of platelet membrane structure<sup>253</sup> or simply are adsorbed<sup>243</sup> remains unresolved, it is of interest that group O platelets become firmly coated by soluble A and B substances added *in vitro*.<sup>241</sup> From a practical point of view it should be noted that the transfusion of ABO incompatible platelets results in lower platelet levels than the transfusion of ABO compatible ones, although the survival time of a sub-population of these ABO incompatible platelets appears to be normal.<sup>210-255</sup> Nevertheless, some workers believe that ABO antigens are either totally absent from platelets or present in very small amounts.<sup>214-261</sup>

Other red cell antigens have not been convincingly demonstrated on platelets,<sup>278</sup> although claims have been made for the presence of *Rh* antigens,<sup>245,246</sup> among others.

### Platelet-Specific Isoantigens

In addition to antigens that platelets share with other cells there are those that appear to be restricted to platelets. Of these, DUZO was the first to be described in detail; others include the  $PI^{A1}$  system, the Ko system, and the  $PI^E$  system (Table 12-4).

### DUZO

The antibody defining DUZO was discovered in the serum of a French mother, Madame Duz., whose four children had died of neonatal purpura.<sup>259</sup> The platelets from 18 of 82 (22%) randomly selected Frenchmen also gave strong reactions with this antiserum. The antigen appears to be absent from red cells and white cells.<sup>252</sup> Later the antibody was described in one other individual.<sup>251</sup> It is not known whether DUZO is related to any of the other platelet-specific antigens.<sup>269</sup>

### $PI^A$ (Zw)

The antibody defining the first antigen of the  $PI^{A1}$  system was described independently by Van Loghem and associates ( $Zw^a$ )<sup>244</sup> and by Shulman and coworkers ( $PI^{A1}$ )<sup>263</sup> who showed that the platelets of about 98% of unrelated individuals readily reacted with it. The identity of the two antigens was established later.  $PI^{A1}$  appears to segregate as a dominant character and clearly shows a dos-

age effect.<sup>264</sup> The antigen is only found on platelets,<sup>280</sup> including those of all monkeys tested, the dog, and the rabbit.<sup>264</sup> Anti-PI<sup>A1</sup> (Zw<sup>a</sup>) antibodies have been found in cases of isoimmune neonatal thrombocytopenia due to maternal isoimmunization,<sup>264</sup> following multiple transfusions, and in individuals suffering from post-transfusion purpura (Chapter 34).<sup>261,269</sup>

Subsequently the product of a gene allelic to PI<sup>A1</sup> (Zw<sup>a</sup>) was described. The antibody defining this allelic specificity (PI<sup>A2</sup> or Zw<sup>b</sup>) was recovered from a patient who had received many transfusions<sup>280</sup> and was shown to react with about 28% of predominantly group O platelets from Dutch individuals.<sup>278</sup> The antigen is only found on platelets and has so far been restricted to those of *Homo sapiens*.<sup>278</sup> Like its allele, PI<sup>A2</sup> (Zw<sup>b</sup>) is inherited as a meelian dominant character. Approximately 69% of Dutch and North American individuals are homozygous for PI<sup>A2</sup>, 3% are homozygous for PI<sup>A2</sup>, and 28% are heterozygotes. The PI<sup>A</sup> (Zw) system does not appear to be closely linked to the ABO, Rhesus, MNS, Duffy, or Ko (see below) systems.<sup>278</sup>

## PI<sup>E</sup>

The PI<sup>E</sup> system appears to contain two allelic antigens, PI<sup>E1</sup> and PI<sup>E2</sup>. The antibodies defining these antigens were originally recovered from a patient who had received many transfusions and from the mother of a baby who had neonatal thrombocytopenia, respectively.<sup>264</sup> The antibodies readily bind complement. Anti-PI<sup>E1</sup> reacts with the platelets from 99.9% of all individuals tested, whereas anti-PI<sup>E2</sup> reacts with only 5%; thus, virtually all PI<sup>E2</sup> individuals must be heterozygotes, and less than 0.1% of the population have been calculated to be homozygous for PI<sup>E2</sup>. PI<sup>E2</sup> appears to be inherited as a dominant character<sup>264</sup> and, while the same probably is also true for PI<sup>E1</sup>, the required criteria for dominant inheritance<sup>259</sup> have not yet been satisfied. The independence of the PI<sup>E</sup> and Ko systems (see below) has not yet been

demonstrated.<sup>269</sup> Platelets from all primates react with anti-PI<sup>E1</sup> but not with anti-PI<sup>E2</sup>.<sup>269</sup>

## Ko

The Ko system is characterized by at least two antigens, Ko<sup>a</sup> (initially called Ko)<sup>279</sup> and Ko<sup>b</sup>.<sup>247,269,278</sup> Ko<sup>a</sup> is found on the platelets of about 13 to 17% of Europeans tested, whereas Ko<sup>b</sup> is almost universally present (> 99% in Holland) (Table 12-4). Both of these antigens are inherited as dominant characters and their allelic relationship has been demonstrated in family studies.<sup>278</sup>

Anti-Ko<sup>a</sup> and anti-Ko<sup>b</sup> antibodies appear to be encountered most commonly in platelet agglutinating sera.<sup>278</sup> Anti-Ko<sup>b</sup> sera behave strangely in absorption studies, however, since the constituent antiplatelet antibody can be absorbed by Ko<sup>b</sup> - (ie, Ko<sup>a</sup>) platelets as well as by Ko<sup>b</sup> + platelets. This may be due to cross-reactivity between Ko<sup>a</sup> and Ko<sup>b</sup> or to the presence of small amounts of Ko<sup>b</sup> antigen in Ko<sup>a</sup> individuals.<sup>278</sup>

The Ko system is not linked to the ABO, Rhesus, Duffy, or Se systems.<sup>221,278</sup> Anti-Ko antibodies apparently do not cause neonatal thrombocytopenia.<sup>230,269</sup>

## Methods of Detection

The two most commonly used methods of platelet typing are thromboagglutination and complement fixation. In the *thromboagglutination test*, platelets are incubated with platelet antibody (or test serum) and the mixture is then examined under the microscope for agglutination. A large number of modifications of this basic test have been described,<sup>222,235,245,274,278</sup> no doubt reflecting the difficulties inherent in the technique. The greatest problem is the natural tendency of platelets to clump even in the absence of antibodies, and this makes interpretation of test results difficult. Attempts have been made to eliminate these nonspecific reactions by the use of EDTA as the anticoagulant,<sup>222,245,278</sup> and by heating<sup>222,245</sup> or washing<sup>270</sup> the platelets. One

of the most successful modifications appears to be that of van der Weerdt,<sup>278</sup> in which platelets are washed in EDTA buffer at 4°C and are kept at this temperature for some time to allow platelet clumps to settle out.

Thromboagglutination appears to be particularly useful for the detection of platelet-specific isoantigens, especially those belonging to the PI<sup>A</sup> (Zw) and Ko systems, which are rarely, if ever, detected by other techniques.<sup>269</sup>

The complement-fixation technique is unsurpassed for HL-A typing of platelets<sup>218,229,261,272</sup> as well as for the platelet specific isoantigens PI<sup>E1</sup> and PI<sup>E2</sup>.<sup>261</sup> Shulman's quantitative technique<sup>261</sup> was later simplified by Aster.<sup>212</sup> The usefulness of this modified technique has been confirmed by a large number of studies.<sup>228,239,249</sup> In one version of this method,<sup>271</sup> 40  $\mu$ l of platelet suspension ( $300 \times 10^9$  platelets/l of 0.1% sodium azide in saline), 40  $\mu$ l of inactivated test serum (56°C for 30 minutes), and 40  $\mu$ l of C' dilution are mixed in a test tube and incubated at 37°C for 60 minutes. The concentration of guinea pig or human complement is adjusted to give 80 to 90% hemolysis in a control. At the end of the incubation period, 100  $\mu$ l of a 3% suspension of antibody-sensitized sheep red cells and 500  $\mu$ l of C' buffer are added and incubated for an additional 60 minutes. The amount of hemolysis seen at this time reflects the fixation of complement by platelet-antiplatelet antibody complexes; no hemolysis indicates complete fixation of complement and therefore the presence of antiplatelet antibodies, whereas hemolysis indicates the opposite. Appropriate controls for the absence of anticomplementary activity in the system as well as to prove the activity of the complement should always be included.<sup>271</sup> With good sera, the reproducibility of the C' fixation test is equal to that of the lymphocytotoxicity test, both of which are in excess of 99%. In addition, platelets are more easily stored than lymphocytes and the C' fixation test is suitable for quantitative purposes.<sup>225,261,271</sup> The test has also been modified to allow the detection of non-complement-fixing (blocking) antibodies<sup>264</sup>

including those found in the serum of some patients with rheumatoid arthritis.<sup>238</sup>

A microtechnique for HL-A typing of platelets by complement fixation requires only 2  $\mu$ l of all test reagents instead of the customary 40  $\mu$ l and promises to be just as reproducible and reliable as the macro method.<sup>217,219</sup> Because of the stability of platelet suspensions, in the future this test may replace the lymphocytotoxicity test for routine histocompatibility testing.

Other tests for the detection of platelet antigens and antiplatelet antibodies include absorption studies,<sup>242,253,257</sup> the antiglobulin consumption test,<sup>229,250,267</sup> mixed cell agglutination,<sup>220,243</sup> clot retraction inhibition,<sup>263,282</sup> platelet factor 3 release,<sup>237</sup> and platelet survival studies.<sup>211,216</sup>

### Nature of Antiplatelet Antibodies

In general, antibodies detected by their complement-fixing properties are IgG, whereas isoagglutinins are IgM.<sup>262</sup> It has been estimated that between 500 and 1,000 antibody molecules per platelet are sufficient to bring about platelet destruction in vivo.<sup>264</sup> This amount of antibody will only occupy about 1% of the total number of antigenic sites on the platelet surface and is too small to be detected by any of the above-mentioned in vitro tests.

### Clinical Significance of Platelet Antigens

Platelet antigens are of clinical significance as transplantation antigens, as a cause of neonatal thrombocytopenia, and as important factors in the success or failure of platelet transfusion therapy.

### Transplantation

Since platelets and other tissues share surface antigens (page 511) it is not surprising that tissue grafts lead to shortened survival of platelets carrying the same antigens.<sup>215,216</sup> Conversely, platelet transfusions may lead to a shortened survival of subsequently applied

tissue grafts.<sup>224</sup> Nevertheless, while platelets have a surface that is about one tenth that of a lymphocyte and the amount of surface antigen per platelet is proportionately reduced,<sup>224,264,269</sup> their immunogenicity is much less than can be explained by differences in size and weight alone.<sup>224</sup> It has been shown, for instance, that 1,000 times more platelets than leukocytes have to be injected in order to induce a second-set skin-graft response.<sup>223</sup> The reason for this difference in immunogenicity is not understood.

### Fetal-Maternal Relations

Isoimmune neonatal purpura<sup>269</sup> is the counterpart of red cell hemolytic disease of the newborn and is discussed in detail elsewhere (Chapter 34). Current serologic techniques reveal platelet antibodies in only half of all suspected cases. The antigens identified in isoimmune neonatal purpura have included the platelet-specific antigens DUZO,<sup>250</sup> PIA<sup>1</sup>,<sup>264</sup> and PIE<sup>1</sup>,<sup>264</sup> as well as several HL-A antigens.<sup>264,273,278</sup> PIA<sup>1</sup> is implicated most frequently,<sup>265</sup> but only when the blocking test is applied, since anti-PIA<sup>1</sup> antibodies do not bind complement. Among the HL-A antigens, HL-A2 is most often responsible.<sup>265</sup>

## Platelet Transfusion

When hemorrhage is due to thrombocytopenia, platelet transfusion is not only practical but frequently it is lifesaving. In most instances the success or failure of such therapy depends on the functional integrity of the transfused platelets, the cause of the platelet defect in the recipient, and the presence or absence of platelet antibodies. Unfortunately the selection of donors is still rather unsophisticated, since routine matching for histocompatibility is not feasible. All of these aspects of platelet transfusion will now be considered in turn.

### Collection and Preservation

Platelets may be transfused in the form of platelet-rich plasma (PRP), platelet concen-

trates (PC), or, occasionally, as fresh whole blood. Blood is collected in conventional ACD-A anticoagulant (Chapter 11) by means of a triple or quadruple pack unit to allow closed handling of the pack's contents. Initially the blood is kept at room temperature and is centrifuged within an hour of collection, usually at 1500 g for six minutes, also at room temperature. The supernatant PRP can then be separated within the closed system. It contains between 75 and 90% of the original number of platelets in the unit. If the blood comes from a routine donor, the resultant packed red cells are stored for use in transfusion (Chapter 11), but if the platelets are obtained by the process of plasmapheresis, then the red cells are immediately returned to the donor and a second unit of blood is obtained. In the latter instance, between 2 and 4 units of blood (1000 or 2000 ml) may be processed at a single sitting, but if more than 2 units are obtained, it is necessary to return about half the platelet-poor plasma following the preparation of platelet concentrates. A donor may give 4 units of platelets each week without experiencing depletion.<sup>309</sup>

In most instances, PRP is further processed to yield platelet concentrates (PC). The PRP is centrifuged at 3000 g for 10 minutes; this concentrates about 95% of available platelets into a button. All but 30 ml of the supernatant platelet-poor plasma is expressed into a third side bag, and may be processed further to yield cryoprecipitate and other plasma components, or it may be returned to the donor. When platelets are used within 24 hours of collection, storage of the platelet button at room temperature will generally make it easy to resuspend platelets without excessive clumping,<sup>313</sup> but a preparation particularly free of aggregates results if the platelets are stored on a slowly rotating disc that is tilted at an angle of 30 degrees to the horizontal.<sup>289</sup> When centrifugation is performed at lower than room temperature, acidification of the PRP has been recommended in order to prevent irreversible clumping of platelets,<sup>288,290</sup> but at room temperature this is not necessary.<sup>289</sup> In addition,

acidification of PRP diminishes the yield of cryoprecipitate from platelet-poor plasma,<sup>288</sup> and, more importantly for present purposes, diminishes the viability of platelet concentrates stored at room temperature.<sup>251</sup>

A number of important biochemical and functional changes occur in platelets during storage, depending in part on the duration and the temperature of storage. Thus, platelets kept at 22°C show a continuous accumulation of lactate, and a dramatic fall in platelet glycogen.<sup>320,321</sup> Total ATP pools do not appear to change markedly either at 22°C or 4°C,<sup>316,320,321</sup> but metabolic ATP is reduced by about half within 24 hours at 4°C, with a corresponding increase in hypoxanthine production.<sup>316</sup> The loss of metabolic ATP is at least partially reversible by inosine.<sup>316</sup> In addition, stored platelets quickly lose their ability to be aggregated by ADP, epinephrine, collagen, and agar.<sup>298,312,321,336</sup> This defect is more marked with storage at 22°C than at 4°C.<sup>336</sup> It also appears to be more severe when platelets are stored as concentrates, rather than as PRP.<sup>312</sup> After transfusion into thrombocytopenic patients, recovery of platelet glycogen and the capacity to be aggregated reappear within 24 hours,<sup>312,321</sup> but this delay may be of crucial importance in a critically ill patient. Glucose utilization through glycolysis, the hexose monophosphate shunt, and the tricarboxylic acid cycle seem to remain intact.<sup>321</sup>

Storage conditions also affect the function and survival of platelets after transfusion. When the <sup>51</sup>chromium technique is used, the yield and survival of autologous platelets stored at 22°C for relatively short periods of time (<24 hours) appear to be much superior to those of platelets stored at 4°C,<sup>296,319</sup> but only if the pH of platelet concentrates is maintained above 6.3.<sup>296</sup> However, when isologous *unlabeled* platelets are given to thrombocytopenic patients after 48 to 72 hours of storage, the yield and survival of platelets are best if the platelets have been stored in the cold.<sup>295,296</sup> In addition, platelets kept at 4°C for 24 to 72 hours are superior to those kept at 22°C with respect to their capacity to shorten the bleeding time and

effect hemostasis, both in patients with thrombocytopenia and in those with platelet defects due to aspirin ingestion.<sup>295,296</sup> The relative ineffectiveness of platelets stored at room temperature for prolonged periods appears to be the result of the more rapid onset of metabolic and functional defects under those conditions (see above). Thus, platelets stored for more than 24 hours prior to transfusion should be refrigerated at 4°C. If platelets are given within 24 hours of collection, storage at ambient temperatures does not adversely affect their function.<sup>296</sup>

Like red cells, platelets may be preserved in the frozen state with the help of *cryoprotective agents* such as glycerol, dimethylsulfoxide (DMSO), dimethyl- and diethylacetamide, and hydroxyethyl starch.<sup>299,301,308,312a,333,331</sup> Frozen platelets should be of great potential value in disaster areas, for shipment to remote places, and for the establishment of autologous depots to be stored before patients undergo intensive chemotherapy or radiotherapy. Unfortunately, cost considerations, possible side effects of cryoprotective agents, and the known loss of viability of frozen platelets have limited the usefulness of cryostorage thus far.<sup>294</sup>

## Matching Procedures

### ABO Antigens

Since A and B antigens are represented on platelets it would seem prudent to transfuse only ABO compatible preparations. Shortened platelet survival is noted when A platelets are transfused into O recipients.<sup>287</sup> Some centers, however, do not consider ABO incompatibility to be of major importance in the treatment of thrombocytopenic patients and ignore ABO types in platelet transfusion therapy.<sup>294</sup> In our present state of knowledge, transfusion of ABO incompatible preparations would appear to be unwise, if avoidable.

### Rh Antigens

Although the evidence for the presence of Rh antigens on platelets is not convincing,

Rh compatibility should be observed when platelets are given to young females suffering from curable or chronic diseases, since red cells invariably contaminate platelet preparations. If Rh incompatibility cannot be avoided and sensitization to Rh antigens is of major concern, anti-Rh immunoglobulin may be given prophylactically (Chapter 27), as in Rh-incompatible pregnancies. In all other situations, Rh typing is unnecessary in platelet transfusion therapy. The risk of Rh sensitization is markedly decreased in immunosuppressed patients.<sup>307</sup>

### Platelet-Specific Antigens

The  $PI^A$  (Zw),  $Ko$ , and  $PI^E$  systems are specific to platelets, but of these only  $Ko^a$  leads to transfusion-induced isoantibodies with a clinically relevant frequency.<sup>270</sup>  $Ko^a$  is mismatched in only 13% of random blood transfusions and when a  $Ko^a$ -negative individual forms anti- $Ko^a$  antibodies, only  $Ko^a$ -negative platelets should be given.

### HL-A Antigens

HL-A antigens constitute by far the most important system of antigens on platelets. They induce antibody formation more readily than do platelet-specific antigens and can greatly diminish the survival time of HL-A incompatible platelets. Sensitization follows repeated platelet transfusion, leukocyte transfusion, tissue transplants, or, most commonly, routine blood transfusion. In virtually all of these, a mismatch for one or more antigens belonging to the HL-A system occurs. Unfortunately, it is impossible to prevent this complication of transfusion therapy in most instances, since it has been estimated that in excess of 20,000 different HL-A phenotypes are possible, and even the most common phenotype (HL-A 1,3,7,8) has a frequency of only 1% in Caucasians.<sup>270</sup> Thus, unless a sibling is to serve as a regular platelet donor, it is presently impractical to match platelets for HL-A antigens routinely, except in major centers where large donor panels are readily available.<sup>173</sup> Platelets from persons having an

almost perfect match are tolerated no better than those from random donors.<sup>339</sup>

The following scheme of donor-recipient matching is employed by most laboratories: (1) Nonimmunized patients are given platelets without regard to HL-A typing. In order to reduce the risk of isosensitization, the number of platelet transfusions should be kept to the lowest quantity that will meet the needs of the patient. (2) If the recipient has siblings, they should always be HL-A typed, since there is a statistical probability that 25% of these will be HL-A identical with the patient. When HL-A identical siblings are available, they are the donors of choice.<sup>309,339</sup> (3) When the yield and survival of transfused platelets are unexpectedly poor, the patient should be HL-A typed and the specificity of the antibody should be established. When antibodies of limited specificity are found, it may be possible to match for platelets not carrying the corresponding antigens. Alternatively, when sibling donors are not available, unrelated compatible donors may be selected by HL-A matching.<sup>340</sup>

### Administration

Platelet concentrates usually are delivered in plastic bags. The contents of several of these are withdrawn into a large plastic syringe and injected into the patient through an appropriate recipient set containing a filter.<sup>286</sup> Because platelet concentrates come with a minimum of plasma (usually 30 ml or less) a relatively large number of platelets remain in the bag. These should be recovered by adding a small amount of saline solution to the contents of the bag. The time interval between phlebotomy of the donor and the injection of platelets into the recipient should be kept as short as possible, the optimum being less than six hours. This will assure superior platelet survival and function.

### Dosage of Platelets

Unless the destruction of transfused platelets is unduly rapid, the increment in circulating platelets will be  $10$  to  $12 \times 10^9/l/m^2$

of body surface for every unit of platelets given (usually  $10^{11}$  platelets per unit).<sup>307</sup> Thus, in a child weighing 30 kg and having a surface area of about  $1 \text{ m}^2$  a platelet rise of  $20$  to  $25 \times 10^9/\text{l}$  could be anticipated following administration of 2 units of platelets. Since the actual yield varies considerably from patient to patient, and from situation to situation for any given patient, it is important to assess yield and survival after platelet transfusions. In order to determine yield, platelet counts are made shortly before and one hour after transfusion. Post-transfusion counts made at 5, 30, 60, and 180 minutes furnish a valuable index of platelet survival in patients with increased platelet turnover rates. When these counts are plotted on semi-logarithmic paper, a rough but useful survival time ( $t/2$ ) may be calculated. More elegant techniques utilizing  $^{51}\text{chromium}$ -labeled platelets are available in some laboratories.<sup>296,319</sup>

The frequency of transfusions will depend on the half-life of transfused platelets, which in most thrombocytopenic patients without antibodies is about two days or less.<sup>307</sup> The half-life of autologous platelets in normal individuals is, of course, much longer (Chapter 9). The platelet count should be followed daily and subsequent transfusions should be guided by changes in these counts and other clinical considerations (see below).

### General Indications

Platelet transfusions are given to stop or prevent bleeding due to thrombocytopenia or abnormalities in platelet function. The critical platelet level at which bleeding occurs varies and depends on (1) the cause of the thrombocytopenia; (2) the presence of concurrent disease such as sepsis, immune vasculitis, or infiltrative diseases such as leukemia; (3) the presence of other clotting defects, as in von Willebrand's disease, disseminated intravascular coagulation, or vitamin K deficiency; and (4) exposure to drugs such as aspirin or others that interfere with the function of the remaining platelets (Chapter 35). The average age of the circulating platelets

also is important, since newly released platelets appear to function more effectively than older ones.<sup>306</sup> This may explain, at least in part, why, at similar platelet levels, patients with thrombocytopenia due to immune destruction tend to bleed less than those with defects in platelet production.<sup>306</sup>

If the function of individual platelets is adequate, life-threatening hemorrhage usually does not occur until the platelet count is less than  $20 \times 10^9/\text{l}$ . Many patients, especially those with thrombocytopenia due to increased destruction, may have no bleeding episodes for long periods of time, even though the platelet count is as low as  $5 \times 10^9/\text{l}$ . However, for patients with other illnesses such as leukemia, the threat of serious hemorrhage has been estimated to be in excess of 1%/day for counts of  $20 \times 10^9/\text{l}$ , with a rise to 20% when the count drops to  $1 \times 10^9/\text{l}$ <sup>305</sup> (Chapter 54). The risk of hemorrhage is particularly great in the presence of fever and infection, or when thrombocytopenic patients are inadvertently exposed to drugs interfering with platelet function. When serious hemorrhage develops, platelets must be transfused as soon as possible and this must be continued until the bleeding is under control.

Indications for prophylactic platelet transfusions are less clear; in general, they are contraindicated in immune thrombocytopenias and in conditions of chronic marrow failure such as aplastic anemia, but are probably indicated in patients with bone marrow suppression due to chemotherapy (see below for details).

### Thrombocytopenias Due to Decreased Production

#### Leukemia (Chapter 54)

Although the frequency of death due to hemorrhage has dropped dramatically with the advent of repetitive platelet transfusions,<sup>311,313</sup> hemorrhage still constitutes the second most common direct cause of death and is undoubtedly a complicating factor in many patients dying from infection. In par-

ticular, the risk of intracranial hemorrhage increases sharply when platelets drop below  $20 \times 10^9/l$ .

Indications<sup>303</sup> for platelet transfusions in leukemia include (1) any overt hemorrhage such as persistent epistaxis and gingival bleeding, or gross hematuria, hematemesis, or melena; (2) intracutaneous hemorrhages and particularly *fresh* crops of petechiae; (3) expanding intramuscular hematomas; and (4) suspected or proven internal bleeding, including cerebral hemorrhage.

*Prophylactic platelet transfusions* are probably indicated in acute leukemia when counts drop below  $10 \times 10^9/l$ . At these levels the risk of hemorrhage is high and the platelet count should therefore be maintained above this figure whenever possible.<sup>303</sup> Patients with  $20 \times 10^9$  or more platelets/l usually do not need prophylactic transfusions unless the counts are dropping rapidly or there is fever, infection, or mucosal ulceration. If a leukemic patient has to undergo a surgical procedure, he should receive enough platelets to raise the count to  $100 \times 10^9/l$  or more.<sup>303</sup>

It is said that isoimmunization and refractoriness to further platelet therapy develop more slowly in patients with leukemia than in those with aplastic anemia, perhaps because of the concomitant use of highly immunosuppressive chemotherapeutic agents.<sup>304</sup> Nevertheless, sensitization does occur<sup>337</sup> and when ordering platelet transfusions it is well to remember that platelet antibody production is at least in part a function of the number of transfusions received. The risk of sensitization is reduced greatly when platelets from histocompatible siblings are used (page 517).

### *Marrow Failure*

Hemorrhage secondary to thrombocytopenia is a common cause of death in patients with aplastic anemia (Chapter 56). Since marrow aplasia may persist for many years, it is imperative that blood and platelet transfusions, especially those from random donors, be given only when absolutely necessary, as isoimmunization will inevitably occur and

make further platelet transfusions ineffective.<sup>309</sup> A number of transfusions (perhaps 15 to 20) are ordinarily required before sensitization becomes evident and prudent restraint will not only delay the appearance of antiplatelet antibodies, but may very well extend the patient's life expectancy. Again, histocompatible siblings are to be preferred to random donors.<sup>339</sup> Because of the prolonged clinical course, prophylactic platelet transfusions are usually not feasible in patients with chronic marrow failure.

When platelets are tagged with very small amounts of antibody, sequestration occurs predominantly in the spleen, whereas larger amounts of antibody lead to hepatic destruction.<sup>291</sup> Splenectomy seems to have resulted in improved platelet survival and decreased transfusion requirements in some patients with aplastic anemia or leukemia.<sup>175,302,309</sup> Benefits are most marked when histocompatible platelets from siblings or unrelated donors are available,<sup>175,309</sup> but in rare instances platelet recovery is also increased when platelets of nonmatched unrelated donors are used.<sup>175</sup>

## **Thrombocytopenias Due to Increased Destruction or Utilization**

### *Immune Destruction*

**ACUTE IDIOPATHIC THROMBOCYTOPENIC PURPURA (ITP).** This disorder is most common in children and is, in most instances, self-limited (Chapter 34). Serious bleeding is uncommon and platelet transfusions are rarely necessary. When platelets are given they are rapidly destroyed, but steroid therapy may sometimes result in improved survival. In chronic ITP the survival of transfused platelets is also very short and under most circumstances it is useless to expose such patients to the risk of multiple transfusions.

**NEONATAL ISOIMMUNE THROMBOCYTOPENIC PURPURA.** Newborns suffering from thrombocytopenic purpura due to maternal antibodies directed against platelet antigens

inherited from the father<sup>269,287</sup> are best transfused with maternal platelets that have been washed in compatible AB serum so as to prevent further transfer of maternal antiplatelet antibody into the baby.<sup>285</sup> The washing procedure is not necessary if histocompatible donors lacking the antigen in question are available, whether this be a platelet-specific or an HL-A antigen. In many instances, maternal siblings constitute the best source of potential platelet donors. The baby's father should *never* be used as a platelet donor.

**DRUG-INDUCED IMMUNE THROMBOCYTOPENIA** (Chapter 34). In most instances of drug-induced immune thrombocytopenia, the majority of which are of the quinine or "innocent bystander" variety, transfused platelets are destroyed rapidly and it is unlikely that platelet transfusions are warranted under such circumstances unless most of the drug has been eliminated.<sup>294,317</sup> Severe febrile reactions may occur.<sup>294</sup>

#### *Nonimmune Destruction or Utilization*

**DISSEMINATED INTRAVASCULAR COAGULATION (DIC)** DIC is one of the most common causes of thrombocytopenia (Chapter 38). Bleeding is not solely due to thrombocytopenia; other causes include depletion of labile clotting factors, vascular damage, and the poor functional state of available platelets. Thus platelet transfusions are unlikely to be of benefit unless the whole process of intravascular coagulation is brought under control. When this is done by appropriate therapy (Chapter 38), platelet transfusions may play a useful role by protecting the patient from hemorrhage due to thrombocytopenia, especially if the patient is receiving heparin. However, in the absence of these definitive measures, platelet transfusions are probably not indicated and may indeed be dangerous as they will undoubtedly participate in further intravascular coagulation.

**MASSIVE TRANSFUSIONS** (Chapter 11). The platelets of patients receiving massive transfusions of stored blood may be washed out of the circulation and thrombocytopenia may

result. Most commonly this occurs following massive gastrointestinal hemorrhage, during major vascular surgical procedures, or in patients with hemorrhagic tendencies who have been inadequately prepared for surgical operations. When the equivalent of one whole blood volume (5,000 ml in a 70-kg man) is replaced with one-day-old bank blood, the platelet count will usually drop to about  $50 \times 10^9/l$ , but lower levels may be reached if more massive transfusions are given. When this occurs, platelet transfusions and/or the exclusive use of absolutely fresh blood are indicated.

A similar depletion of circulating platelets may take place if stored blood is used in infants receiving exchange transfusions for hemolytic disease of the newborn. Considering the small volume of blood required, the use of stored blood constitutes an unnecessary risk in this procedure.

Patients on extracorporeal circuits frequently develop thrombocytopenia because the blood used to prime the pump is usually not absolutely fresh and, even if it is, platelets are destroyed within the bypass circuit. In addition, a defect in platelet function also has been demonstrated.<sup>335</sup> In order to prevent postoperative bleeding, platelets may be given at the completion of the operation.<sup>338</sup>

**THROMBOCYTOPENIA DUE TO SPLENIC POOLING.** Massive splenomegaly is frequently associated with a moderate degree of thrombocytopenia because of the pooling of platelets within the spleen (Chapter 45). Under most circumstances, platelet levels do not fall below  $60$  to  $80 \times 10^9/l$  and no hemorrhagic tendencies develop. However, a critical decrease in platelets may occur during acute bleeding episodes and platelet transfusions then become mandatory. Because of the trapping of platelets in the spleen, a large number of platelets may have to be given in order to obtain the desired increase.<sup>294</sup> Platelet transfusions also may be required during portocaval shunt procedures; concentrated platelets should be available before the start of the operation, as they cannot usually be obtained quickly enough in an emergency.

### Qualitative Platelet Defects

Patients with *congenital abnormalities* of platelet function (Chapter 35) do not usually require platelet transfusions except to control specific bleeding episodes or to prepare for a surgical procedure. Under such circumstances, platelet transfusions effectively prevent or control hemorrhage. When the platelet defect is acquired, and especially when it is related to an abnormal plasma environment, therapy may not be as effective. Thus the acquired platelet defect that is found in uremic patients is best corrected by dialysis<sup>315</sup>; in the absence of dialysis, transfused platelets quickly acquire the same defect as that present in the patient's own platelets. When the platelet defect is due to acquired causes such as the ingestion of aspirin or other drugs interfering with platelet function (Chapter 35), the response to transfusion is much more favorable. For, while the platelet defect due to aspirin may be discernible for a week,<sup>314</sup> the intact drug is quickly hydrolyzed.<sup>314</sup> As a result, platelets given even a few hours after aspirin ingestion no longer acquire the same defect, even though free salicylate is still detectable in the circulation.

### Complications

The complications of platelet transfusion are not as common or serious as those accompanying whole blood transfusion. They include (1) febrile transfusion reactions, (2) infectious hepatitis, (3) bacterial contamination, and (4) post-transfusion purpura. *Febrile transfusion reactions* would appear to be mostly due to infusion of incompatible leukocytes contaminating platelet preparations,<sup>269</sup> since purified platelet preparations do not cause febrile reactions in sensitized recipients.<sup>278</sup> It has been suggested, however, that serotonin released from sensitized and sequestered platelets may cause flushing.<sup>269</sup> In general, patients with febrile reactions have lower post-transfusion increments in circulating platelets than do those without these reactions. The reactions are self-limited and may occur immediately or as long as 12 hours

after transfusion; they rarely last more than 24 hours. Chills are frequent and hives have been observed. The dangers of *infectious hepatitis* have been described in Chapter 11. *Bacterial contamination* may be a problem if platelets are stored at room temperature,<sup>297</sup> but this danger is minimized by using a closed collecting system and observing good technique during the collection and processing of blood. The problem of *post-transfusion purpura* has been discussed elsewhere (Chapter 34).

though the conditions that result in anemia encompass nearly the full spectrum of human disease, an orderly approach to the diagnosis in the patient with anemia is usually fruitful.

"Anemia" is not a diagnosis in itself, but merely an objective sign of the presence of disease. The correct diagnostic terminology for a patient with anemia requires the inclusion of the pathogenesis of the anemia (eg, iron-deficiency anemia, due to carcinoma of the colon; anemia of chronic renal disease; hemolytic anemia due to administration of alpha-methylpapa). The reason for this is simple and fundamental: the correct treatment requires an understanding of the pathogenesis of the condition (Chapter 1).

Furthermore, as discussed in Chapter 3, it is necessary to think of the circulating red cells and of the bone marrow from which they arise as a single functional entity, to which the term "erythron"<sup>22</sup> has been applied. The erythron includes the normoblasts at all stages of maturation and the reticulocytes, as well as the erythroid-committed stem cells (Chapter 2) which lack morphologic features to identify them as precursors to red cells, and, in the circulation, the mature red cells. In the bone marrow, the interstitial tissue of the erythron is made of reticulum, fine capillaries, and fat. In the circulating portion of the erythron, the plasma acts as interstitial tissue. In addition to serving as the medium of transport for the red cells from the lungs to the other tissues, plasma also is the continuing source of glucose for the met-

THE detection and diagnosis of anemia are frequently the focus of attention in the care of patients because accurate quantitation is not difficult to achieve and rational analysis of the problem is possible. Even

abolic activities of the erythrocytes (Chapter 3) and the means for removal of its catabolic products. Although plasma is normally isotonic with red cells, its high sodium and low potassium concentrations present a hostile ionic environment for which the erythrocyte must compensate by active metabolic work (page 100). When they fail to do so, hemolytic disease results (Chapter 20). Other adverse factors that may be presented by the interstitium include antibodies that react with red blood cells and may lead to destruction of the main substance of the erythron (Chapter 27).

"Atrophy" of the erythron may occur in aplastic anemia (Chapter 56), whereas hypertrophy occurs in polycythemia vera (Chapter 30). In addition, since the hematopoietic system functions as a physiologic unit, when erythropoiesis is stimulated, as a rule it is found that there is increased leukopoiesis and increased thrombopoiesis. Thus, following acute blood loss and in hemolytic anemia, there may be not only reticulocytosis but also moderate or even marked leukocytosis accompanied by a greater number of the younger forms of leukocytes than are ordinarily present ("shift to the left"). The quantity of platelets in the circulation is also likely to be increased.

The diseases afflicting the erythron may be considered in the same categories as those affecting other organ systems, viz, congenital (Chapters 21 to 26) or acquired disease (Chapters 14 to 19; 27 to 29); those due to hypoplasia or atrophy (Chapter 56), neoplasia (Chapter 46), infection (Chapter 18), trauma (Chapter 28), the action of physical (Chapter 28) or chemical (Chapter 23) substances, and so forth. Often more useful for diagnostic purposes, however, are classifications based upon the altered physiology of the erythron in disease states. These classifications are discussed later in this chapter.

## The Approach to the Diagnosis

The first step in the diagnosis of anemia is the detection of the presence of anemia per

se. This requires the accurate *measurement* of the pertinent values, as discussed in Chapter 1, and comparison of these values with suitable *reference values* for healthy individuals, given in Appendix A. The second step is the investigation of the pathogenesis of the anemia. Sufficient regard for the first step is required if one is to avoid the performance and expense of needless diagnostic studies and treatment of nonexistent anemia, as well as the converse, overlooking the presence of slight anemia and thereby neglecting an important clue to the presence of a disease that might be readily amenable to treatment.

The term "anemia," as it is generally used in clinical medicine, refers to a reduction below normal in the *concentration* of hemoglobin or red blood cells in the blood. The concentration is best measured as the VPRC rather than by enumeration of the red blood cells, because the VPRC offers greater precision and accuracy, and also greater ease of standardization and maintenance of equipment, than do other approaches. Simple but accurate methods are discussed in Chapter 3. Alternatives to the VPRC are discussed in Chapters 1 and 3. As explained there, measurement of hemoglobin is a satisfactory alternative but does not provide other useful information. Strict attention to technique and standardization is required no matter what method is applied, if *meaningful diagnoses* are to result.

It must be remembered that the mean normal value and the lower limits of the "normal" range depend upon the age (childhood or adult life) and gender of the subjects, as well as the altitude of residence. After puberty, the values for males are higher than for females. Apart from these differences, one must be wary of a laboratory that assigns normal values or ranges that differ from the established values cited here. Either inaccuracy in measurement or faulty selection of the reference population is implied, and inaccurate results of work done on patients must also be suspected.

The selection of a reference population is fraught with problems.<sup>3, 4, 123, 145</sup> Nevertheless, the physician must not equate locally

prevalent values with normal values. To do so would erroneously lead to the conclusion that in a particular subpopulation or geographic region a different, lower standard applies. This error has been made in surveys of large populations. Rather than recognize the prevalence of anemia, some authors have advised that the lower limit of normal values for women must be set below the values given previously by Wintrobe,<sup>140</sup> or subsequently by WHO<sup>145</sup> and the AMA Council on Food and Nutrition.<sup>3</sup> It has been found that 20 to 30% of some populations surveyed in the United States<sup>74</sup> and in Sweden<sup>56,61,133</sup> have iron-deficiency anemia. To have accepted such persons as normal by reducing the lower limit of the normal hemoglobin to 10.2 g/dl<sup>74</sup> or 11.5 g/dl,<sup>56</sup> in order to coincide with the observations in the survey population, is a disservice to patients and misleads physicians.<sup>115</sup> Strict adherence to the values listed is advised. Even though statistical interpretation of normal distribution curves leads us to expect that 2.5% of a healthy population might have hemoglobin or hematocrit values lower than 2 SD below the mean, the burden of proof is on the physician to show that disease is absent in every patient in whom the hemoglobin or hematocrit values fall below the limits cited in Appendix A.

Regarding anemia, it is important to have a clear concept of the distinction among three measurements: (1) the total number or volume of red blood cells in the circulation (the "red cell mass"); (2) the total quantity of blood, meaning red blood cells and plasma, in the circulation (the "blood volume"); and (3) the ratio of these two (the "body hematocrit"), which is a measure of concentration and is closely reflected by the venous blood hematocrit, red blood cell count, and hemoglobin concentration. Reduction in blood volume has been called "oligemia" or "hypovolemia," and reduction in the red cell mass has been called "oligocythemia." The distinction between a reduction in the concentration and a reduction in the total quantity of red cells is required for clinical practice, but the term "oligocythemia" is used less

often than the phrase "reduction in red cell mass" to express the latter finding. Conceptually, a reduction in the total quantity of red blood cells or hemoglobin in the circulation may be a correct definition of anemia, but it is not a practical one.

In the great majority of instances, when oligocythemia is present the total blood volume remains at nearly normal values because of compensatory expansion of the plasma volume. Consequently, as a rule, the reduction in the concentration of red blood cells very nearly reflects the reduction in the total quantity of red blood cells in the circulation. The same is true for the concentration and total quantity of hemoglobin. These facts generally obviate the need for the measurement of the blood volume to appraise the reduction in the red cell mass. The exceptions to this rule are acute blood loss, and the limited number of clinical situations that are accompanied by a significant reduction or increase in the plasma volume; these are listed in Table 13-1. An important reason that the total quantity of hemoglobin or red cells in the body is not generally used as a measure of anemia is that measurement of the blood volume requires the time-consuming and sophisticated techniques of dye or isotope dilution methods (Chapter 3). These are not suitable for broad application in large numbers of patients, nor for often-repeated determinations in a given individual.

"Spurious anemia," that is, a subnormal concentration of red blood cells due to hemodilution, as occurs in the third trimester of pregnancy,<sup>20,32,123,198</sup> is not a disorder of erythropoiesis or of the erythron and should not be treated as such. Likewise, when an increased concentration of red blood cells is found, the physician must distinguish between secondary erythrocytosis and polycythemia vera (Chapter 30) on the one hand, and hemoconcentration, due to a chronic or an acute reduction in plasma volume, on the other. In the latter, clinical signs of dehydration, hypotension in the upright posture, poor skin turgor, and high values for urine specific gravity are guiding clues. More difficult is the detection of chronic anemia in patients in

**Table 13-1. Conditions in Which There Is a Significant Disproportion between the Hematocrit and the Red Cell Mass**

- 
- A Relative increase in plasma volume** Hematocrit disproportionately low
- 1 Hydræmia of pregnancy
  - 2 Overhydration in oliguric renal failure, or congestive heart failure
  - 3 Chronic diseases and hypoalbuminemia (sometimes)
  - 4 Laennec's cirrhosis
- B Relative decrease in plasma volume** Hematocrit may be high, normal or low but is high relative to the red cell mass
- 1 Dehydration, especially saline loss
    - a Protracted diarrhea (especially in infants) cholera
    - b Intestinal malfunction (pyloric obstruction, etc.)
    - c Abdominal paracentesis with fluid restriction
    - d Peritoneal dialysis with hypotonic solutions
    - e Diabetic acidosis
    - f Extended fluid deprivation
    - g Diabetes insipidus with restricted fluid intake
  - 2 Stress erythrocytosis spurious polycythemia
- C Decrease in both plasma volume and red cell mass** Hematocrit normal, red cell mass low
- 1 Acute blood loss
  - 2 Cancer (sometimes)
  - 3 Myxedema Addison's disease panhypopituitarism
- 

whom the reduced red cell mass is masked by an associated contraction of the plasma volume.<sup>13, 17, 36, 52, 100</sup> In acute conditions, the true scope of the anemia becomes evident when hydration and homeostasis are restored. In some chronic conditions, anemia may be partly or completely masked even in the face of adequate hydration; measurement of the red cell mass or of the plasma volume is needed to appreciate the true situation.<sup>13, 17</sup> For example, hypotension on induction of general anesthesia has been attributed to hypovolemia in patients with a normal hematocrit, when the underlying disease has been carcinoma,<sup>13, 18</sup> pheochromocytoma, hypertension, or hypothermia, or when vasopressors have been administered.<sup>2</sup> Hypovolemia, perhaps as a consequence of diuretic therapy,<sup>2</sup>

also was noted in a patient with mitral stenosis and regurgitation who was scheduled for valvulotomy.

## Manifestations of Anemia

Symptoms in patients with anemia depend on five factors: (1) the reduction in the oxygen-carrying capacity of the blood, (2) the degree of change in total blood volume; (3) the rate at which (1) and (2) have developed, (4) the associated manifestations of the underlying disorder that resulted in the development of anemia, and (5) the capacity of the cardiovascular and pulmonary systems to compensate for the anemia. There is a wealth of clinical experience indicating that the hemoglobin concentration is not the sole determinant of the symptoms that may be expected, nor of the urgency with which measures must be taken to correct the anemia. Furthermore, coexistent disease, for example, coronary insufficiency or chronic obstructive bronchopulmonary disease, may become significantly symptomatic with a degree of anemia that would be well tolerated under other circumstances.

If the anemia has been insidious in onset, and cardiopulmonary disease is absent, the patient's adjustment may be so good that the hematocrit may be 0.25 l/l or less, and the hemoglobin concentration 8 g/dl or lower, before the patient has sufficient symptoms<sup>44</sup> to appreciate his true situation. It is not uncommon for patients with iron-deficiency anemia, pernicious anemia, or other types of chronic anemia to have their hemoglobin concentration fall to 6 g/dl before they are motivated to seek medical attention.<sup>45</sup> In children, particularly, there may be little apparent restriction of capacity for physical exertion, despite the presence of severe anemia.<sup>39</sup> The physiologic adjustments that take place chiefly involve the cardiovascular system and changes in the hemoglobin-oxygen dissociation curve. These will be discussed shortly.

The symptoms of acute hemorrhage, which are discussed in Chapter 19 (page 695), are chiefly related to hypovolemia, rather than to

anemia. Depending on the amount of blood lost, there may be no symptoms, mild hypotension, or progressively severe degrees of shock.<sup>135</sup>

### Acute Hemolytic Reaction ✓

When there is an acute hemolytic reaction, there may be acholuric jaundice; and, if intravascular hemolysis occurs, there may be hemoglobinemia, methemalbuminemia, and hemoglobinuria, as well as fever and abdominal or back pain. These are related to the sudden release of hemoglobin, and to its destruction and disposal (Chapter 20). They occur in addition to the cardiorespiratory symptoms that result from the anemia per se.

### Chronic Anemia

In chronic anemia, the reduction in the concentration of the oxygen-carrying pigment in the blood has a more meaningful correlation with the cardiovascular adjustments that must be made than does the magnitude of the deficit in the total quantity per se of red blood cells or of hemoglobin in the circulation. The amount of oxygen delivered to the tissues by a given volume of blood is a function of (1) the concentration of hemoglobin, (2) the percent saturation of hemoglobin with oxygen, (3) the hemoglobin-oxygen dissociation curve, and (4) the tissue oxygen tension. When fully saturated with oxygen, 1 g of hemoglobin will bind 1.34 ml of oxygen. At a normal hemoglobin concentration, 100 ml of arterial blood contains about 20 ml of oxygen, whereas the same volume of mixed venous blood contains approximately 15 ml, the difference—amounting to about 25% of the initial quantity of oxygen—being accounted for by the extraction of oxygen by the tissues. If a patient's hemoglobin concentration were only 7.5 g/dl, then only about 10 ml of oxygen could be carried per dl of arterial blood. If tissue oxygen consumption is to be maintained in anemia, and there were no adjustments in the circulation, both the percent saturation of mixed venous blood and the tissue oxygen

tension would have to fall, and the percent utilization of arterial oxygen would increase. It follows, then, that the quantity of blood that must be pumped by the heart to the tissues, per minute, would be inversely related to the blood hemoglobin concentration if the other factors were invariable. In fact, however, the hemoglobin-oxygen dissociation curve does shift in chronic anemia, so that there is a reduction in the affinity of hemoglobin for oxygen,<sup>8,73,78,101,106</sup> which is helpful, as noted below, but a reduction in the arterial oxygen saturation<sup>101,109</sup> also occurs and this is disadvantageous. The demand for a greater cardiac output is first accomplished by an accelerated heart rate, rather than by a change in stroke volume.<sup>24,50</sup> Hence, tachycardia at rest and especially upon small exertion is characteristic of the patient with moderate or greater degrees of anemia.

### 2,3-DPG

The binding and release of oxygen by hemoglobin are profoundly affected by the variations in the concentration of 2,3-diphosphoglyceric acid (2,3-DPG) which are known to occur in the red cell in disease.<sup>7,28,60</sup> (Also see Chapter 3, page 107.) The oxygen affinity of hemoglobin is reduced as the concentration of 2,3-DPG increases, and the converse is also true.<sup>62</sup> An increase in red cell 2,3-DPG is found in chronic anemia.<sup>16,34</sup> This facilitates the delivery of oxygen to the tissues by reducing the affinity of hemoglobin for oxygen at the oxygen tensions found in capillaries.<sup>98,130</sup> At alveolar oxygen tensions, the small change in oxygen affinity that is due to the increased red cell 2,3-DPG does not significantly affect the uptake of oxygen by the red cells in the lungs. The net result favors the heart by allowing the tissues to extract oxygen during exercise at a lower cardiac index for an equivalent oxygen consumption and work load than otherwise would be the case.<sup>98</sup> It has been calculated that DPG-induced changes in hemoglobin affinity for oxygen may compensate for up to half the oxygen deficit in anemia.<sup>98</sup>

## Cardiovascular Adjustments

The cardiac index generally is increased in anemia, and the arteriovenous oxygen difference is narrowed.<sup>24,116</sup> Central venous and intracardiac pressures are not altered, although at times the right atrial pressures may be elevated. The total circulating blood volume may decrease,<sup>21</sup> although this does not occur uniformly.<sup>122</sup> When the hemoglobin concentration is less than 7 g/dl, the cardiac output is nearly always increased,<sup>24</sup> and when it is less than 5 g/dl, the increase in cardiac index has been found to be due mainly to an increase in stroke volume and, to a lesser extent, in heart rate,<sup>107,108</sup> even with exercise. By contrast, in persons without anemia the increase in cardiac output accompanying exercise is mainly due to tachycardia. In children with severe anemia, the mean cardiac index was found to be approximately the same as in adults with equally severe anemia. However, in children this state was achieved by greater tachycardia and a lesser increase in stroke volume than in comparably anemic adults.<sup>29</sup> Nevertheless, the capacity of children with chronic anemia to endure exercise burdens generally is excellent.<sup>279</sup> If congestive heart failure develops, there is usually some underlying heart disease, but the latter may not be the case in adults if the hemoglobin concentration is less than 5 g/dl.<sup>12,59,107,132</sup> In sickle cell anemia, heart failure has occurred at less severe degrees of anemia.<sup>75</sup>

Cardiac compensation may be marginal in severe anemia, and congestive heart failure may be precipitated by blood transfusion<sup>59</sup> unless precautions are taken<sup>19</sup> (Chapter 11). As the cardiovascular system adapts to anemia, generally the velocity of blood flow is increased<sup>18,107,108</sup> and hence the circulation time is shortened; this condition may persist even with the development of congestive heart failure.<sup>54</sup> Studies have shown that mild or moderate anemia is accompanied by a greater coronary flow per unit of left ventricular work; ultimately, however, when the hemoglobin concentration is reduced below

half of normal, reduction of ventricular function is observed, presumably because the coronary flow has approached maximum.<sup>31</sup> Whereas reflex vasoconstriction is a feature of the response to acute blood loss,<sup>50</sup> in chronic anemia the peripheral vascular resistance is lowered, and this plays a dominant role in the high-output, hyperkinetic circulatory response.<sup>48</sup> Increasing peripheral resistance, as with methoxamine or orthostatic stress, reduces cardiac output.<sup>48</sup>

Changes in peripheral resistance are regional, rather than generalized. Muscle blood flow is increased, whereas skin blood flow is reduced.<sup>1</sup> Cerebral blood flow is increased.<sup>66</sup> Renal blood flow is diminished.<sup>33</sup> Usually the systemic and pulmonary artery systolic pressures are unaffected, but the diastolic pressures are lower.<sup>107</sup>

Cardiac enlargement in anemic patients is ascribed to dilatation. In rats made anemic by iron deficiency, however, cardiac hypertrophy occurred. The total quantity of protein, RNA, and DNA in the myocardium was increased, but their concentrations were unchanged.<sup>77</sup>

## Respiratory and Circulatory Symptoms

Many times, respiratory and circulatory symptoms are only noticeable following exertion or excitement; however, when the anemia is sufficiently severe, dyspnea and awareness of vigorous or rapid heart action may be noted even at rest.<sup>24</sup> A humming or whirring sound in the head, which is attributed to the rapid blood flow through cranial arteries, may be bothersome to the patient and signal the point at which significant anemia has developed. The rapidity of the onset of anemia, its severity, the age of the patient, and the capacity of the cardiovascular system to adjust to it govern the clinical presentation. When anemia develops rapidly, shortness of breath, tachycardia, pallor, "dizziness" or faintness, particularly upon arising from a sitting or recumbent posture, and extreme fatigue are prominent. In chronic anemia, only moderate dyspnea or palpitation may

anemias due to the deficiency of specific substances and can be treated successfully.<sup>6</sup> When achlorhydria is present, it is common for the patient to have a stool in the morning, immediately on arising, and one or two later in the day.<sup>7</sup> Bouts of diarrhea are not uncommonly misconstrued as "intestinal flu." Change in stool habits may be an important lead to neoplasms of the colon and rectum underlying the anemia.<sup>8</sup> The possibility of blood loss must be considered. The significance of tarry stools is often not appreciated by patients, and specific inquiry is necessary. The amount of blood lost from hemorrhoids may be overlooked by patients, or overestimated. In men, occult blood loss is most often from the gastrointestinal tract. In women, in addition to the preceding, it is necessary to appraise the actual amount of blood lost during menstruation, although this is notoriously inaccurate if only a routine inquiry is made. The number of pregnancies and abortions, and the interval since the most recent of these, is also important, for each represents significant iron loss. In a child or adolescent, the rate of growth is noteworthy.

<sup>1</sup> The dietary history is quite important but it is difficult to obtain an accurate one. It is obviously not sufficient to learn that the patient eats certain foods. It is important to know how much or how little of these foods is consumed, and to remember that the patient may deliberately deceive the physician because of embarrassment over eating habits or financial restrictions. The patient must be questioned regarding the diet, meal by meal, and quantitative information should be obtained if at all possible. A record regarding dietary idiosyncrasies and cooking habits may be valuable, especially with reference to folic acid intake.<sup>2</sup> Changes in weight are most important.

<sup>3</sup> The presence or absence of fever must be known, for if present it suggests infection, lymphoma or other neoplasm, or collagen disease.<sup>4</sup> Inquiry regarding cough, pleurisy, and hemoptysis is important since either infection or neoplasm may be causes of the anemia.<sup>5</sup> Pains in the limbs, paresthesias, and difficulty in walking suggest pernicious ane-

mia.<sup>6</sup> Abnormal color of the urine, suggesting blood or hemoglobin, may signify urinary tract disease or hematologic problems. Bilirubin does not occur in the urine in uncomplicated hemolytic anemia, but a darker than normal color may result from the increased excretion of urobilinogen and its conversion to urobilin.

<sup>7</sup> Bruises, ecchymoses, and petechiae are other important points in the history. Their presence indicates that the disorder producing the anemia is not confined to the erythron, and that an additional disturbance of the other marrow elements or of the liver must be sought. Alternatively, the anemia itself may be the consequence of blood loss resulting from a disorder of hemostasis.

In all instances, the presence or absence of symptoms suggesting an underlying disease such as chronic renal disease, chronic infection, an endocrinopathy, or malignancy must be explored.

The physical examination should include a careful evaluation of the optic fundi and the nervous system. Scleral icterus should not be overlooked, and it should be recalled that the yellowish cast of incandescent lights will obscure it. Careful palpation for sternal tenderness should not be omitted. In acute leukemia (Chapter 47), rather frequently one will find a small, acutely tender area near the mid or lower third of the sternum of which the patient may have been quite unaware. This can be easily overlooked unless it is particularly sought out, as it is frequently present even in the absence of tenderness of the bones of the extremities. A systematic check for palpable enlargement of the lymph nodes must be made, with reference to infection, lymphoma, leukemia, and metastatic carcinoma (Chapter 40).<sup>5</sup> The heart cannot be ignored, for murmurs may yield the first evidence of subacute bacterial endocarditis, thereby explaining the presence of anemia. In the abdominal examination, in addition to palpation of the liver and spleen, the kidneys should be given attention. Physical examination may reveal the first clue to renal cell carcinoma as the cause of obscure anemia. Neither the pelvic nor the rectal examination can be ne-

glected, for tumor or infection in these regions may also cause anemia.

Even when the color of the *urine* does not suggest blood, the routine urine analysis should include a test for occult blood. This simple, confirmatory procedure should also be performed when hemoglobinuria is suspected, or apparent. However, a positive reaction may also be due to hematuria or even myoglobinuria. *Hematuria* may be differentiated from the other conditions by finding red blood cells upon microscopic examination of the urine, or by centrifuging a fresh urine specimen and thereby clearing the bloody color from the supernatant portion and depositing the red blood cells in the bottom of the tube. Hematuria may be the result of disease of the kidneys or urinary tracts themselves, or the consequence of thrombocytopenia or of acquired or congenital abnormalities of the blood coagulation system. The sickle cell trait may be accompanied by innocuous hematuria.

The finding of hemoglobinuria implies intravascular hemolysis, which is usually a very serious situation. One must be careful not to confuse true hemoglobinuria with the release of hemoglobin into the urine from lysis of red cells in a specimen that has stood a while prior to examination. The circumstances surrounding routine urine analyses by large laboratories may obscure this important distinction, unless the physician or the clinical pathologist personally intervene.

## Morphologic Features in Anemia

So much information can be obtained from the examination of the stained blood film that it is always worthwhile for the trained physician to examine it himself. In clinical practice, reliance is too often placed on technicians for blood examinations. Whereas, under ordinary circumstances, most of the quantitative determinations are too time-consuming to be done by the physician, microscopic examination of the blood film can be made in a short time with great benefit resulting. This also serves as a check on the blood counts. Our approach for evaluating the

blood film is detailed in Chapter 1. The value of the VPRC as a simple, quick, and accurate aid to the physician has been discussed (page 115). Together, the blood film and the VPRC, including inspection of the hematocrit tube to determine the icterus index and the volume of packed white cells and platelets (VPW & PI) (Frontispiece), may allow solution of the diagnostic problem.

The forms and structure of the red blood cell are evaluated and compared with the red cell indices; polychromasia of erythrocytes is noted if present; and any abnormalities of the leukocytes or platelets are observed (page 27). Such an examination quickly and easily identifies cases of *macrocytic anemia* (Chapter 14), *microcytic-hypochromic anemia* (Chapter 16) (Table 13-3), and the spherocytosis and polychromasia indicative of *hemolytic anemia* (Chapter 20). The finding of *oval macrocytes*, particularly when accompanied by neutropenia, hypersegmented neutrophils, relative lymphocytosis, and sometimes thrombocytopenia, suggests *megaloblastic anemia* (Chapter 14). Marked *polychromatophilia* of the red blood cells implies a high reticulocyte index, hence accelerated red cell production. When erythropoiesis is stimulated, as, for example, following *acute blood loss*, there may be not only *reticulocytosis* but also moderate or even marked *thrombocytosis* and *leukocytosis* accompanied by an increase in the younger forms of leukocytes not ordinarily seen in such numbers in the blood ("shift to the left").

Other strong clues regarding the cause of the anemia can be adduced from the examination of the blood film (Table 13-3). The presence of *helmet cells* and other *schistocytes* implies a microangiopathic or traumatic type of *hemolytic anemia* (Chapter 28), and should also suggest the possibilities of *uremia*<sup>45</sup> and *malignant hypertension*.<sup>28</sup> *Target cells* suggest the presence of the abnormal hemoglobins C<sup>129</sup> and E<sup>33</sup> (Chapter 24), *thalassemia* (Chapter 26), *liver disease with jaundice*,<sup>38</sup> or the post-splenectomy state<sup>40,119</sup>; they also are seen in obstructive jaundice.<sup>38</sup> *Leptocytes* (Gr. *leptos*, fine) are thin erythrocytes, usually of normal or slightly greater than normal diameter, which occur in heterozygotes for thalas-

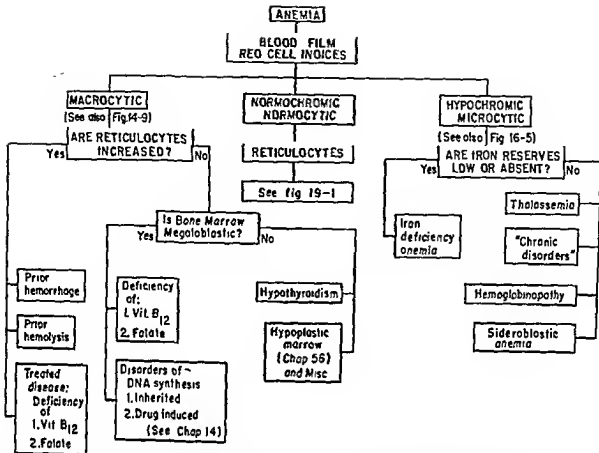

Fig 13-1. Diagram to illustrate successive steps in the differential diagnosis of anemia beginning with the examination of the blood smear and the measurement of red cell indices. The history and physical examination may make it unnecessary to carry out the subsequent steps, namely, reticulocyte index, bone marrow examination, and evaluation of iron reserves as judged by serum iron and total iron-binding capacity and staining of bone marrow for iron.

semia even when target cells are not evident (Chapter 26). The discovery of normocytic-hypochromic erythrocytes on microscopy, in the face of microcytic-normochromic red cell indices, is the hallmark of leptocytosis. This combination of findings, especially when accompanied by basophilic stippling of the red cells, suggests heterozygosity for a thalassemia gene (Chapter 26). The finding of a mixture of hypochromic and normochromic erythrocytes in an anemic patient who had not been transfused or treated with iron ("dimorphic anemia") suggests a sideroblastic anemia (Chapter 18). Elliptocytes, wherever they occur,<sup>11,70</sup> are a readily recognized indication of an anomaly of the red cell that may be accompanied by hemolytic disease (Chapter 21).<sup>11</sup> They may also be found in thalassemia and other conditions (Chapter 20).

A variety of red cells with one or more spiny projections has been described ("spicule cells") and of these two types can be distinguished, acanthocytes and echinocytes. Acanthocytes are red cells with several irregularly spaced, large and coarse projections on their surface, which vary in width and length.<sup>23</sup> They may resemble spherocytes with pseudopods (Chapter 20) and typically are seen in a rare syndrome characterized by steatorrhea, retinal degeneration, mild hemolytic anemia, and deficiency of betalipoprotein (Chapter 21).<sup>94</sup> Similar cells (spur cells) are described in a severe hemolytic syndrome accompanying Laennec's cirrhosis.<sup>37,70,118,121</sup> (Chapter 19) and have been seen in association with hemolytic anemia in metastatic liver disease.<sup>72a</sup> Such cells may also be found in fresh, wet preparations. In contrast, in echinocytes

Table 13-3. Description and Significance of Various Forms of Red Corpuscles

Type of Cell	Description	Physiologic Significance	Clinical Disorders
Macrocyte	Larger than normal ( $> 8.5 \mu\text{m}$ diameter) Well filled with hemoglobin	1 Young RBC (skipped generation early loss of nucleus) 2 DNA synthesis impaired megaloblastic maturation	1 Accelerated erythropoiesis 2 $B_{12}$ or folate deficiency
"Thin" macrocyte	Diameter increased but MCV normal, often hypochromic (see target cell)	Membrane cholesterol and lecithin increased	Liver disease post splenectomy
Hypochromic cell	Exaggeration of normal central pallor usually also microcytic	Failure of hemoglobin synthesis due to 1 lack of iron 2 defective globin synthesis 3 defective porphyrin synthesis	1 Iron deficiency anemia anemia of chronic disease (?) 2 Thalassemia, some hemoglobinopathies (C, E) 3 Sideroblastic anemias
Target cell	Hypochromic, with central pigment, thin cell surface/volume ratio increased	1 Splenectomy decreases rate & extent of loss of lipids from reticulocytes 2 Accumulation of both cholesterol and phospholipid on RBC 3 Congenital	As for hypochromic cells; also 1 post splenectomy 2 in liver disease, especially obstructive jaundice 3, LCAT deficiency Thalassemia
Leptocyte	Thin, hypochromic cell, diameter normal, MCV decreased		
Microcyte	Smaller than normal ( $< 7.0 \mu\text{m}$ )	Differs according to whether or not it is 1 well filled with hemoglobin 2 shape is normal	See below
Spherocyte	Spherical, not hypochromic, usually also microcytic, surface/volume ratio decreased	1 RBC membrane abnormality 2. RBCs lose fragments after impact with fibrin strands, walls of diseased vessels, and artificial surfaces in the circulation	1 Hereditary spherocytosis 2. Acquired immunohemolytic anemia

<i>Elliptocyte</i>	Elliptical in shape, not hypochromic	1 Hereditary abnormality 2 Acquired alteration	1 Hereditary elliptocytosis 2 In various anemias, especially megaloblastic
<i>Sickle cell</i>	In shape of sickle, form assumed especially on deprivation of oxygen	Molecular aggregation of Hb S	Hb S trait or disease Also seen with Hb I, Hb C <sub>Capetown</sub> , Hb C <sub>Philadelphia</sub>
<i>Schistocyte</i>	Helmet- or triangular-shaped, fragmented or greatly distorted RBC, smaller than normal	RBC lose fragments after impact with fibrin strands, walls of diseased vessels, and artificial surfaces in the circulation	1 Microangiopathic hemolytic anemia 2 Hemolytic anemia due to physical agents 3 Also in uremia, malignant hypertension
"Teardrop" RBC	Shape of drop, usually microcytic often also hypochromic	Distorted or fragmented RBC	1 Especially in myelofibrosis 2 Less frequently in other forms of anemia; eg thalassemia
<i>Spicule cell</i> may be (a) <i>Acanthocyte</i> ( "spur cell" )	RBC with spiny projections on surface Has 5 to 10 spicules of various lengths irregular in spacing and thickness	Differs according to type (a) Ratio of cholesterol/lecithin of RBC membrane increased when associated with liver disease Can be converted to normal shape by non-ionic detergents	1 In abetalipoproteinemia 2 Liver disease with hemolytic anemia 3 Post splenectomy (few) 4 Pyruvate kinase deficiency
(b) <i>Echinocyte</i> (Sea urchin cell crenated cell, burr cell)	Has 10 to 30 spicules, evenly distributed over surface of RBC	(b) Result of alteration of intra- and extra-cellular environment Can be brought about by accumulation of fatty acid or lyssolecithin on RBC surface or both, as result of changes in plasma or in RBC metabolism	1 Uremia, bleeding peptic ulcer, Ca stomet 2 Commonly artifactual 3 Pyruvate kinase deficiency
<i>Pyknotocyte</i>	Distorted and contracted RBC, similar to echinocyte		"Infantile pyknotocytosis"
<i>Stomatocyte</i>	Uniconcave, as contrasted with normal biconcave RBC, slit-like instead of central pallor in RBC	1 Hereditary Primary defects in membrane structure or function resulting in abnormalities of cation permeability, content and flux 2 Acquired alteration in cation content and flux	1 Hereditary stomatocytosis, several forms 2 Smaller numbers seen in alcoholic cirrhosis, acute alcoholism, obstructive liver disease, malignancies, etc, and perhaps as artifact

("sea urchin" cells) or burr cells the spicules are regularly spaced and more uniform in size and more numerous than the projections of acanthocytes. Echinocytes essentially resemble artificially produced crenated cells. They have been described in uremia, carcinoma of the stomach, and in acute blood loss.<sup>114</sup> There are conflicting views regarding their origin. The original report considered them to be true poikilocytes because they could be seen in wet preparations.<sup>114</sup> However, in many instances they may well be true crenated red cells formed during the preparation of the blood film.<sup>41</sup> It has also been proposed that they result from rupture of marginal, intra-erythrocytic vacuoles.<sup>15</sup> The finding of spicule distortions of erythrocytes also should suggest the possibility of the pyruvate kinase type of hemolytic anemia,<sup>96</sup> although spicules are not unique to this disorder.<sup>92</sup>

Stomatocytes are erythrocytes with a well-demarcated silt-like appearance instead of the usual circular zone of central pallor (Fig. 13-2).<sup>82,90</sup> Hemolytic anemia of severe<sup>82</sup> or mild<sup>91</sup> form accompanies the hereditary anomaly. Stomatocytes are not as uncommon as once thought<sup>47 83,96</sup> (Chapter 20).

Sickle cells characterize the disease due to the presence of the anomalous hemoglobin S in the erythrocytes (Chapter 25). When sickle cells are present on the ordinary blood film the diagnosis of sickle cell anemia, or one of the closely related sickle-hemoglobin syndromes, is strongly suggested. However, sickle-like cells can also be produced in the absence of hemoglobin S (page 845). Intra-erythrocytic crystals suggest the hemoglobin SC syndrome (Chapter 25).

Teardrop-shaped poikilocytes suggest myelofibrosis or other myelophthitic processes, especially when normoblasts and a few immature granulocytes are also seen on the blood film (Chapter 57). Howell-Jolly bodies are most commonly found after splenectomy, but may also be an indication of splenic atrophy following multiple infarctions (page 832), hemolytic anemia, or megaloblastic anemia (page 569). Cabot rings also are seen in these disorders.

If any of the above are detected, the diagnostic possibilities regarding the anemia are sharply narrowed. For further steps in the evaluation and treatment of the indicated condition, one should follow the procedures discussed in the corresponding chapters of this book.

### Roentgenography (X-ray)

When the history, physical examination, and initial evaluation of the blood and urine have not led to the recognition of an underlying disease process that explains the anemia, the examination should be supplemented by roentgenography. A roentgenographic film of the chest may suggest pulmonary tuberculosis or other infection, or unsuspected mediastinal enlargement due to lymphoma or other malignant disease. Roentgenograms of the bones may lead to the discovery of osteolytic lesions due to multiple myeloma or metastatic carcinoma; or of tumors, periosteal elevation suggesting leukemia, or even osteosclerosis.

### Radioisotope and Erythrokinetic Studies

The use of radioisotopes and the study of erythrokinetics (Chapter 4) are unnecessary for diagnosis in the great majority of cases of anemia, although they have been important in helping to elucidate the pathogenesis of many forms of anemia and in arriving at a diagnosis in some cases in clinical practice. These and other procedures involving special laboratory equipment and techniques, which previously were done only in certain large medical centers, are now available at many hospitals throughout the world. However, correct operation of the equipment and conduct of the technical aspects does not assure a useful result. The interpretation of the data in disease is even more difficult than in the normal state, because many of the assumptions upon which the normal model was created need not apply equally in different disease states. Changes in the red cell mass, or the rate of erythropoiesis during an erythro-

kinetic study or during measurement of red cell survival with radioisotopes, may invalidate interpretations based on comparison with normal values established in the "steady-state."

When the clinical evaluation with the accompanying simple blood, urine, and roentgenographic studies does not permit identification of the cause of the anemia, it is best to proceed with an evaluation of the mechanisms of red cell production and destruction.

## Classification of Anemia

### Pathogenetic Classification

Broad pathogenetic groups are the basis of one system of classification (Table 13-4). Thus, anemia may be attributed to (1) loss of blood, (2) excessive destruction of mature red cells, and (3) impaired red cell production. This system of classification implies a preliminary analysis and classification of data in order to place the case into one of the three main groups and one of several principal subgroups. Certain conditions, however, can be classed equally well in two or more locations; eg, although pernicious anemia is the result of a conditioned nutritional deficiency (Chapter 15), it is associated with signs of accelerated red cell destruction.

### Morphologic Classification

Morphologic classification of anemia (Table 13-5) was the natural result<sup>141</sup> of the advances made in the study of the blood through laboratory observations. It has proven to be of practical clinical value. Characteristic changes in the size and the hemoglobin content of the red corpuscles occur in some of the various types of anemia that have been listed in the pathogenetic classification. For that reason, classification on morphologic grounds is helpful in differentiating these anemias, and treatment may be guided to some extent by such observations, as will be shown later in this chapter.

Underlying the morphologic classification is the observation that when anemia develops

**Table 13-4. Pathogenetic Classification of Anemia**

- I Blood loss**
  - A Anemia after recent hemorrhage (acute)
  - B Anemia after persistent hemorrhage (chronic)
- II Excessive destruction of erythrocytes (hemolytic disease)**
  - A Extracorpuscular factors
    - 1 Antibodies
    - 2 Infection (malaria, etc.)
    - 3 Splenic sequestration and destruction
    - 4 Associated disease states, eg lymphoma
    - 5 Drugs, chemicals, and physical agents
    - 6 Trauma to RBC
  - B Intracorpuscular defects
    - 1 Hereditary
      - a Disorders of glycolysis
      - b Faulty synthesis or maintenance of reduced glutathione
      - c Qualitative or quantitative abnormalities in synthesis of globin
      - d Abnormalities of RBC membrane
      - e Erythropoietic porphyria
    - 2 Acquired
      - a Paroxysmal nocturnal hemoglobinuria
      - b Lead poisoning
- III Inadequate production of mature erythrocytes**
  - A Deficiency of essential substances
    - 1 Iron, folic acid, vitamin B<sub>12</sub>
    - 2 Protein
    - 3 Possibly ascorbic acid
    - 4 Experimentally: copper, cobalt, pyridoxine, niacin, riboflavin, possibly pantothenic acid, thiamin
  - B Deficiency of erythroblasts
    - 1 Atrophy of bone marrow: aplastic anemia
      - a Chemical or physical agents
      - b Hereditary
      - c Idiopathic
    - 2 Isolated erythroblastopenia ("pure red cell aplasia")
      - a Thymoma
      - b Chemical
      - c Antibodies
  - C Infiltration of bone marrow
    - 1 Leukemia, lymphoma
    - 2 Multiple myeloma
    - 3 Carcinoma, sarcoma
    - 4 Myelofibrosis
  - D Endocrine abnormality
    - 1 Myxedema
    - 2 Addisonian adrenal insufficiency
    - 3 Pituitary insufficiency
    - 4 Sometimes, hyperthyroidism
  - E Chronic renal disease
  - F Chronic inflammatory diseases
    - 1 Infections
    - 2 Noninfectious diseases, including granulomatous and collagen diseases
  - G Cirrhosis of liver

Table 13-5. Morphologic Classification of Anemia

Morphologic Type of Anemia	Underlying Abnormality	Clinical Syndromes	Treatment
<b>I. Macrocytic (MCV &gt; 94, MCHC &gt; 31) <i>glu</i></b>			
<b>A Megaloblastic</b> (for details see Table 14-3)	1 Vitamin B <sub>12</sub> deficiency	Pernicious anemia, etc	Vitamin B <sub>12</sub>
	2 Folic acid deficiency	Nutritional megaloblastic anemias, sprue & other malabsorption syndromes, etc	Folic acid
<b>B Non-megaloblastic</b> (see Table 14-1)	3. Inherited disorders of DNA synthesis	Orotic aciduria, etc	According to nature of disorder
	4 Drug-induced disorders of DNA synthesis	Chemotherapeutic agents	Stop offending drug
	1 Accelerated erythropoiesis	Anticonvulsants, oral contraceptives	Folic acid
	2 Increased membrane surface area	Hemolytic anemia Response to hemorrhage Hepatic disease, obstructive jaundice, post splenectomy	Treatment of underlying disease
	3 Obscure	Myxedema Hypo- & aplastic anemia etc	
<b>II Hypochromic-microcytic (MCV &lt; 80, MCHC &lt; 31)</b>			
	1 Iron deficiency, (for details see Table 17-3)	Chronic loss of blood, inadequate diet, impaired absorption, increased demands etc	Ferrous sulfate & correction of underlying cause
	2 Disorders of globin synthesis	Thalassemia alone or with a hemoglobinopathy (Table 28-1 and 26-3)	Nonspecific
	3 Disorders of porphyrin & heme synthesis	Pyridoxine-responsive anemia, etc (Table 18-2)	Pyridoxine
	4 Other disorders of iron metabolism (Table 16-2)	See Table 16-2	
<b>III Normochromic-normocytic (MCV 82-92, MCHC &gt; 30) (See Table 19-1)</b>			
	1 Recent blood loss	Various	Transfusion, iron Correct underlying condition
	2 Overexpansion of plasma volume	Pregnancy Overhydration	Restore homeostasis
	3 Hemolytic diseases (Table 20-3)	See Table 20-3	According to nature of disorder
	4 Hypoplastic bone marrow (See Table 56-1)	Aplastic anemia Pure red cell aplasia	Transfusions, stop drug Androgens
	5 Infiltrated bone marrow	Leukemia, multiple myeloma, myelofibrosis, etc	Chemotherapy, etc
	6 Endocrine abnormality	Hypothyroidism adrenal insufficiency, etc	Treatment of underlying disease
	7 Chronic disorders	See Table 18-1	Treatment of underlying disease
	8 Renal disease	Renal disease	Treatment of underlying disease
	9 Liver disease	Cirrhosis	Treatment of underlying disease

MCV, mean corpuscular volume, in fl; MCHC, mean corpuscular hemoglobin concentration, in g hemoglobin/dl.  
 > greater than; < less than

there is not always a proportionate decrease in the number of red corpuscles, the quantity of hemoglobin, and the volume of packed red cells per unit volume of blood. When the average size or the average hemoglobin content of the red cells is altered, disproportionate changes in the measures of anemia occur. These are detected by computing the *red cell indices* (Chapter 3) and confirmed by the direct observation of the red cells on the *stained blood film* (Chapter 1). Characteristically, certain diseases cause a greater decrease in the number of red cells than in the hemoglobin or red cell mass. This reflects the fact that in those conditions the majority of the red cells produced are larger than normal, a situation that is termed "*macrocytic anemia*" and is characterized by a high MCV (page 566). In other diseases, the converse may occur; namely, there may be a proportionately greater decrease in the quantity of hemoglobin and in the volume of the red cell mass than in the total quantity of red cells. In such cases, the majority of red cells are smaller than normal; this is termed "*microcytic anemia*" and is characterized by a low MCV (page 621). In such cases, in addition to alterations in the size of the red cells, there usually is a proportionately greater reduction in the total quantity of hemoglobin than in the total quantity of red cells. This reflects a reduction in the *concentration of hemoglobin within the individual red cells*; it is termed "*hypochromic anemia*" and is characterized by a low MCHC (page 621). Finally, anemias in which, on the average, the red cells are not altered in size are called "*normocytic anemias*," and, if the MCHC is also normal, they are termed "*normochromic-normocytic anemias*."

If one first classifies anemia on morphologic grounds as described above, and then lists some of the etiologic factors that may be grouped under these categories (Table 13-5), it becomes apparent that this approach is very helpful in limiting the diagnostic possibilities when either macrocytic or microcytic-hypochromic anemia is discovered. However, it is less useful if the anemia proves to be of the normocytic type, because of the many and diverse diseases included in this

subgroup. In the latter circumstance, *kinetic considerations* regarding red cell production and destruction are very helpful in arriving at an etiologic diagnosis.

### Erythrokinetic Classification

The number of erythrocytes present in the circulation at a given time is the result of a *dynamic equilibrium* between the *production* and *delivery* of red cells into the circulation on the one hand, and their *destruction* or *loss* from the circulation on the other. Anemia can be construed to be primarily due to an alteration either in production or in destruction, or in both of these factors. From this simple concept, it is possible to develop an understanding of anemia based on the mechanism of its development. The basic data required for such an analysis of anemia are listed in Table 13-2.

The normal homeostatic mechanisms of the body bring about recovery from anemia by accelerating erythropoiesis. In an otherwise healthy individual who sustains acute anemia, whether as a volunteer blood donor or by hemorrhage as a result of trauma or disease, one finds an increase in the daily rate of production and release of new red cells into the circulation. This results in a reticulocytosis, the magnitude of which is related to the degree of the anemia. The reticulocyte count gradually returns to normal values as the normal red cell mass is restored. If anemia is persistent, then one of three explanations will obtain: erythropoiesis may be diminished or even virtually absent (*insufficient erythropoiesis*); or, even if erythropoiesis is accelerated to maximum values, it may be inadequate to compensate for continued loss of red cells by either hemorrhage (*continued bleeding*) or destruction of mature red cells within the body (*uncompensated hemolytic disease*); or, erythropoiesis may be stimulated but *ineffective* insofar as delivery of mature erythrocytes to the circulation is concerned.

The first questions to be answered in determining the kinetic basis for a given case of anemia are: "*Is erythropoiesis accelerated?*" and "*Is it effective?*" If the answers are, "Yes," then either the hematocrit should be rising

and the patient recovering or, if the anemia persists despite the delivery of greater than normal numbers of red cells to the circulation daily, there must be either persistent blood loss or active hemolytic disease.

Often hemolytic anemia is suspected because there are signs of increased bilirubin production. The plasma may be distinctly icteric, and the van den Bergh reaction reveals an increase in unconjugated ("indirect") bilirubin. Examination of the urine in such cases reveals it to be free of bilirubin, but an increased quantity of urobilinogen is present. It is useful, where the facilities exist, to measure the quantity of urobilinogen excreted in the stool as well. As a rule, in *acute* and in many instances of *chronic hemolytic anemia*, in addition to the pigmentary evidence just mentioned, increased blood destruction is also accompanied by reticulocytosis, leukocytosis, and thrombocytosis (Chapter 20). When exceptions to this rule are found, one should consider the diagnoses: paroxysmal nocturnal hemoglobinuria (Chapter 29), disseminated lupus erythematosus or other collagen disease, and lymphoma (Chapters 51 and 52).

The reticulocyte count or index (Chapter 20) provides the most simple and practical estimate of effective red cell production. If the reticulocytes are increased and serial measurements show that the patient is recovering from the anemia, then one of three mechanisms may have been responsible for the anemia: (1) a self-limited or discrete episode of hemorrhage; usually the history allows a decision in this regard, although sometimes melena may have occurred and the patient has not appreciated its significance; (2) a self-limited or discrete episode of hemolysis that has terminated with the removal of a chemical or physical agent, or the end of a transient, associated disease process that induced it (Chapter 20); or (3) a treated nutritional deficiency, (eg, of iron, vitamin B<sub>12</sub>, folic acid), in which treatment had been administered to the patient prior to the current examination, with or without a precise diagnosis.

When the reticulocytes are normal or low, erythropoiesis is presumed to be impaired.

Two general varieties of impaired erythropoiesis must be considered, namely, *insufficient erythropoiesis* and *ineffective erythropoiesis*.

Insufficient erythropoiesis is associated with a quantitative lack of erythroid precursors. In extrauterine life in man, erythropoiesis normally occurs exclusively within the bone marrow. Absence of the normal cellular constituents of the bone marrow, and their replacement by fat, results in the clinical syndrome of *aplastic anemia* (Chapter 56). If only the erythroid cell line is affected, the term "pure red cell aplasia" is used (Chapter 56). Infiltration and replacement of the bone marrow by leukoblasts, myeloma cells, myeloid tissue (chronic myelocytic leukemia), lymphocytes (chronic lymphocytic leukemia, lymphosarcoma), neoplastic cells, granulomas (tuberculosis, histoplasmosis, sarcoidosis), or fibrous tissue (myelofibrosis) are also associated with anemia (Table 13-4). It has been assumed that the infiltration has the same untoward effect on erythropoiesis as does atrophy of the bone marrow, but this assumption has never really been proved. In both of these instances the reticulocyte count tends to be reduced or normal. When all of the marrow precursors are affected, pancytopenia may result.

The diagnostic clues to infiltration of the bone marrow are: (1) normoblasts together with immature granulocytes in the circulation, (2) teardrop and other odd-shaped poikilocytes, and (3) neutropenia or thrombocytopenia, or bizarre platelets in the circulation.

Both hypoplasia and infiltration can be detected by examination of the *bone marrow*, first by aspiration, and, if that procedure yields only a hypocellular specimen, by *biopsy* (Chapter 2). Such studies reveal the cytologic and histopathologic characteristics, respectively, in the small region that had been selected for study. An infiltrative process may be demonstrated or the marrow may be found to be hypoplastic. If the marrow is normally cellular or nearly so, and does not have abnormal elements but erythropoiesis is reduced, the underlying cause may be renal

disease, endocrinopathy (Chapter 19), or certain chronic disorders (Chapter 18); or, sparsely distributed infiltrative elements, such as tumor cells or granulomas, may have been missed.

Ferrokinetic studies can serve as a functional test of the erythroid marrow as a whole (Chapter 4). For example, reduced plasma iron transport (PIT), combined with a reduced erythrocyte iron turnover (EIT), can establish that functional erythroblasts are deficient in the marrow considered as a totality. Although rarely essential, such studies complement those made on the biopsy sample of marrow and thereby reduce the likelihood of error due to an inadequate sample. Other patterns of ferrokinetic measurements of diagnostic value can also be recognized.<sup>53</sup> These can be used to classify anemia in a patient, and thereby point to the underlying disease, when other measures fail. For example, hemolytic anemia, myeloid metaplasia, chronic infection, and similar disorders have characteristic patterns on erythrokinetic measurement (Chapter 4).

The term "ineffective erythropoiesis" is used to refer to the production of erythrocytes that are so defective that they are destroyed before they leave the marrow or very shortly thereafter. Some degree of erythropoiesis is ineffective even in normal subjects (Chapters 3 and 5); however, in certain conditions, especially megaloblastic anemias, thalassemia, and sideroblastic anemias, ineffective erythropoiesis becomes greatly exaggerated. Under these circumstances, (1) the *effective* production rate appears to be considerably less than the *total* production rate, and/or (2) the rate of heme catabolism greatly exceeds that which can be accounted for by the rate of destruction of circulating red cells. *Total* production is assessed by evaluating the erythroid cellularity of the bone marrow or by measuring the plasma iron transport rate (Chapter 4, page 164). Measures of *effective* production include the reticulocyte count or index (Chapter 20) and the erythrocyte iron turnover rate (Chapter 4, page 165). When greatly increased, the excessive heme catabolism accompanying ineffective erythropoiesis

can result in an increased unconjugated bilirubin level in the plasma. Lesser degrees can be detected by measuring endogenous carbon monoxide production or fecal urobilinogen excretion (Chapter 20). These measures will be found to exceed the theoretical values for heme breakdown calculated from a red cell survival study (Chapter 5). The bilirubin produced by ineffective erythropoiesis, unlike that derived from circulating cells, acquires an "early label" from isotopic glycine (Chapter 5).

## Treatment of Anemia

The optimum treatment of anemia requires the eradication of its cause or, if that is not possible, at least modification of the underlying disorder. This necessitates the correct diagnosis, as already discussed. The general measures are purely accessory to this objective.

### Blood Transfusion

Transfusion of blood is a valuable temporary measure for the treatment of chronic anemia if the cardiovascular compensation is inadequate, or if the magnitude of the anemia is such that cardiovascular collapse is threatened. The indications for blood transfusion are discussed in Chapter 11 (page 475). The risks involved also need to be considered. Needless to say, if there is acute or chronic blood loss, the bleeding should be arrested, and volume replacement made when acute blood loss exceeds 15% of the estimated blood volume.

### General Measures

When anemia results from infections, *treatment of the infection*, whether requiring surgical or antibiotic therapy, is the correct treatment for the anemia. The administration of iron, folic acid, and vitamin B<sub>12</sub> is of no value in such cases except when there is a concurrent deficiency of one of these substances. In subacute bacterial endocarditis, military tuberculosis, or osteomyelitis, pa-

its may present with marked anemia and presence of the infection may be difficult to establish, its very existence being doubted if it is finally proven after diligent search. In these instances, and in other cases of anemia due to infection or associated with other chronic disorders, the treatment of the underlying disease is the correct treatment for the anemia.

In acquired hemolytic anemia due to drugs, in aplastic anemia, one of the most important actions that can be taken is the removal of the patient from exposure to the offending agent. It should not be forgotten that malarial infection produces acute anemia that is hemolytic in nature.

For the patient with anemia, a well-balanced diet should be given. The classical experiments of Whipple and his coworkers<sup>137</sup> established the basis for present knowledge of the effect of various foods on hemoglobin production. These ultimately led to the discovery of the value of liver therapy for pernicious anemia and may be regarded as having initiated the modern era of hematology by stimulating the shift in emphasis from physiologic to physiologic investigation. In dogs made anemic by bleeding and fed almost-bread ration deficient in a number of nutritional factors, animal organs such as liver, kidney, and chicken gizzard were found to be the most efficient of all the foods in promoting hemoglobin regeneration. Dairy products were the least effective, whereas vegetables were second only to liver. Fruits, such as apricots, peaches, prunes, raisins, fresh grapes, and apples, were found to be of greater value than the chlorophyll-containing vegetables such as spinach and beet greens. The value in these foods can now be ascribed to their content of protein, as well as folic acid, vitamin B<sub>12</sub> and other vitamins, and iron and other minerals.

Liver is a complex mixture rich in proteins and their subunits, as well as iron, and vitamins including folic acid and cobalamin. It is the mainstay of treatment for pernicious

anemia, first by the oral route and later by the parenteral administration of concentrates, liver therapy is now outmoded. For the treatment of pernicious anemia, it has been replaced by injections of crystalline cobalamin (Chapter 14, page 590). Except for exceedingly rare cases of a peculiar type of anemia,<sup>68</sup> liver may now be considered only as a part of a balanced diet, rather than a specific therapy for anemia.

Vitamins are obtained in sufficient amount from the balanced diet; except for the presence of specific nutritional deficiency, the addition of supplementary amounts will not accelerate the recovery from anemia. Thus, the administration of ascorbic acid is associated with improvement when scurvy is present, but it does not appear to serve a specific function in hematopoiesis. Even though pyridoxine deficiency may be induced experimentally in animals, and "pyridoxine-responsive" anemia is known in humans (page 680), the latter is not due to deficiency of pyridoxine. Amounts of vitamin B<sub>6</sub> adequate for human nutrition are obtained from a diet that is otherwise satisfactory with reference to protein, vitamins, and minerals. Accordingly, the administration of pyridoxine and other vitamins and minerals as a nonspecific nutritional supplement is unnecessary, and involves a needless expense.

Foods such as pastry and "soft drinks," which are high in carbohydrates but deficient in the substances mentioned above, should be avoided as they tend to displace other, balanced foods. Indeed, just as nutritional anemia may be induced by faulty diet or cooking,<sup>30,64,72</sup> so may the recovery from anemia be hampered. The consistency of the food and the number of feedings must be adjusted to the state of health of the patient. Tasteful preparation and service of the food will avoid monotony of diet and help the ill patient with anorexia overcome the inclination to accept no more than a minimal diet.

### Other Measures

Other measures in the general treatment of anemic patients are similar to the measures

employed in the treatment of any patient with an acute or chronic disease. Physical rest, fresh air, sufficient sleep, and freedom from anguish are valuable and important. Physical exertion to the point of actual fatigue should be avoided, but graded exercise should be prescribed according to the patient's strength and general well-being. It must be remembered that when anemia is marked the cardiac reserve may be minimal. Particularly in elderly patients, angina pectoris, congestive heart failure, or cardiac arrhythmias may be present and would require treatment. Consideration should be given to the physical strain placed upon the patient by diagnostic studies, such as sigmoidoscopy, barium enema, gastroscopy, or bronchoscopy. In some instances, in order to avoid cardiac complications it is necessary to transfuse the patient with concentrated red cells before undertaking such studies. In general, with the successful treatment of anemia, respiratory and circulatory symptoms will be alleviated and angina pectoris may vanish as the hemoglobin concentration rises. Digitalis glycosides and diuretic agents, which may be necessary for the control of congestive heart failure when anemia is present, may not be required after the anemia has been relieved.

### Administration of Substances Specifically Lacking

#### *General Considerations*

In the discussion of the classification of anemia, it was pointed out that, of the macrocytic anemias, the type characterized by megaloblasts in the bone marrow most frequently results from a lack of vitamin B<sub>12</sub> or folic acid. The clinical syndromes associated with these deficiencies are listed in the tables of this chapter and are discussed fully in Chapters 14 and 15. The development of our knowledge concerning the role of these substances in hematopoiesis has been described in Chapter 4.

The detection of hypochromic-microcytic anemia presents a special challenge to the physician. The clinical syndromes of iron-

deficiency anemia are discussed in Chapter 17. In most cases, chronic blood loss is implied and the source must be discovered. Simply administering iron is not enough. The finding of such an anemia is often the first signal of pathologic blood loss, as is fully explained there (page 641).

When anemia is due to deficiency of a substance essential for erythropoiesis, such as vitamin B<sub>12</sub>, folic acid, or iron, administration of the agent lacking will be followed by a very gratifying therapeutic response. Of paramount importance, however, is the understanding that these substances exert a salutary, therapeutic effect in the treatment of anemia only when deficiency of the specific substance is the limiting factor in erythropoiesis. Furthermore, only rarely will deficiency of two or more of these substances occur simultaneously. Successful treatment requires foreknowledge of the correct diagnosis, and choice of the correct agent.

### *Therapeutic Response*

Descriptions of the therapeutic response to the administration of substances that are specifically lacking, such as vitamin B<sub>12</sub>, folic acid, and iron, are given in the chapters dealing with these deficiencies, namely, Chapters 14 and 17. There also the importance of replenishing body stores of these essential nutrients is discussed and therapeutic regimens are outlined. Here it need be stated only that, in the vitamin-deficiency states, the response to administration of the substance that is lacking is extraordinarily rapid and occurs following administration of very small quantities of that substance. The response to iron therapy is less dramatic but equally specific.

**THERAPEUTIC TRIAL.** An optimal hematologic response to the administration of a vitamin or mineral constitutes the ultimate demonstration that deficiency of the administered nutrient was the limiting factor in erythropoiesis. This principle underlies the use of the therapeutic trial for diagnostic purposes. Although specific assays for serum vitamin B<sub>12</sub>, folate, and iron (Chapters 14 and 16)

have largely replaced the diagnostic therapeutic trial in clinical practice, there still are circumstances in which trials may be useful. For one thing, they are readily available to physicians who may not have access to laboratories performing the more complex assays. For another, serial trials may help to sort out the relative importance of multiple deficiencies in complex cases.

In conducting a therapeutic trial, it is important to establish baseline conditions by performing determinations of reticulocyte counts daily and measuring VPRC or hemoglobin two or more times, preferably for 7 to 10 days before the agent to be tested is given. Then the agent is administered, usually in a minimally effective dose, and daily measurements of reticulocytes and repeated determinations of VPRC are continued. The trial is considered to be positive if a significant reticulocytosis occurs within 10 days after administration of the agent was commenced. Values for the expected peak reticulocyte count at various degrees of anemia are given in Table 14-7 (page 594) for the megaloblastic anemias; the expected rate of VPRC increase appears in Figure 14-11 (page 595). In the case of iron therapy in iron-deficiency anemia, the increase in reticulocytes is generally slower to appear and not as great as in the megaloblastic anemias (Chapter 17).

The use of minimally effective doses is especially important in therapeutic trials in the megaloblastic anemias because patients with vitamin B<sub>12</sub> deficiency will respond to large doses of folate, and those with folate deficiency may respond to large doses of vitamin B<sub>12</sub>.<sup>65,147</sup> The minimal effective dose for vitamin B<sub>12</sub> is 1 to 2 µg per day<sup>125</sup> and that for folate is 200 µg per day. These doses induce a hematologic response only in patients deficient in the administered vitamin.

**DOUBLE RETICULOCYTE RESPONSE TECHNIQUE.** This provides a very useful method for clinical investigation.<sup>89</sup> It may be used to establish the minimum dose of a substance that can achieve an optimum hematologic response, or to evaluate the presence of concomitant deficiencies of two substances. After

the reticulocytes have returned to normal following the first therapeutic trial, a second trial is conducted with either a larger dose of the same substance or a particular dose of another substance. If a second reticulocyte response occurs, and the second trial entailed a higher dose of the same substance, it implies that a suboptimal dose was used in the first trial. If the second trial employed a different compound, either a deficiency of both compounds is implied or the response to the first substance was nonspecific.

### "Shotgun" Treatment

"Shotgun" treatment consists in the indiscriminate use of several therapeutic agents simultaneously, each of which is effective individually in specific types of anemia, without first determining their applicability to the case at hand. Also in the treatment of anemia, it refers to the use of pharmaceutical mixtures which include vitamins and minerals, deficiency of which diligent study has failed to establish as a cause of disease in humans.<sup>142</sup> Iron, folic acid, vitamin B<sub>12</sub>, riboflavin, pyridoxine, niacin, copper, possibly ascorbic acid, adrenal corticosteroids, androgenic steroids, and antibiotics have specific indications for treatment of anemia. However, the general use of fixed combinations of multiple agents for therapy is irrational. Combinations of agents deprive the physician and the patient of the important evidence that a response to specific therapy can provide, namely, the confirmation of the diagnosis. A combination of several therapeutic agents is sometimes prescribed out of ignorance of the diagnosis in the hope that one of the ingredients will hit the mark (ie, bring about an increase in the hemoglobin concentration) even though one did not know where to aim; hence, the term "shotgun therapy." Sometimes they are prescribed for their principal ingredient, usually iron, without an appreciation on the physician's part that they are, in fact, a shotgun mixture.

The use of multiagent, "shotgun therapy" is strongly condemned. Merely bringing about an increase in the hemoglobin concen-

tration is an unsatisfactory result and constitutes inadequate therapy. A plan for further management is an essential ingredient of the treatment of anemia. That plan depends upon knowledge of the underlying cause of the anemia.

In addition to the medical considerations against the use of "shotgun" preparations, the physician must also be concerned with their excessive cost which is in part a reflection of the inclusion of ingredients that are unnecessary for the treatment of the patient at hand.<sup>142</sup> Medicolegal considerations also cannot be ignored.

### Splenectomy

Splenectomy is of greatest value in the treatment of the patient with anemia of hereditary spherocytosis (page 756). It is sometimes helpful, but not curative, in the hemolytic anemia of pyruvate kinase deficiency (page 773), and in some patients with acquired hemolytic anemia who have a positive reaction to Coombs' antiglobulin test, when adrenocorticosteroid hormones are required in such large doses and for so long a time that their use is impractical. Splenectomy is sometimes of benefit in aplastic anemia (page 1763), and rarely so in thalassemia (page 869). In Banti's syndrome, congestive splenomegaly with anemia, leukopenia or thrombocytopenia, splenectomy may be undertaken with the possibility of improvement, provided all other causes of the splenomegaly and cytopenias have truly been excluded by careful evaluation (Chapter 46). Too often, a diagnosis of "Banti's disease" or "hyper-splenism" is attached when in reality the anemia and splenomegaly are due to lymphoma or other disease in which splenectomy would not relieve the anemia. In Felty's syndrome, splenectomy does not appear to be of lasting benefit. In selected patients with myeloid metaplasia with splenomegaly, splenectomy is helpful; but in others, in whom the spleen plays a major role in compensatory, extramedullary hematopoiesis, splenectomy could, at least theoretically, aggravate the anemia (Chapter 57).

### Hormones

Of the hormones, the use of thyroxine or equivalent compounds will be curative in the anemia of myxedema, but not beneficial for anemia of other causes. Cortisone, prednisone, and related *adrenal glucocorticoid hormones* will relieve the anemia of Addisonian adrenal insufficiency, even when given in small amounts. However, their more frequent application is in the treatment of acquired hemolytic anemia of the auto-antibody type (page 914). Here, given in pharmacologic rather than physiologic doses, they are very potent in the control of anemia. The same hormones are valuable in the induction of a remission of acute lymphoblastic leukemia, thereby allowing recovery from the accompanying anemia. They have been considered to stimulate erythropoiesis because reticulocytosis may follow their administration (even in pernicious anemia in relapse), and erythroid hyperplasia of the bone marrow may develop, nucleated red cells may appear in the circulation,<sup>144</sup> and polycythemia may ensue. However, in disease states with anemia, other than those noted above and in certain cases of "pure red cell aplasia," a useful erythropoietic effect cannot be obtained with prednisone or related compounds.

Glucocorticoids are particularly useful when they are needed only for short periods of time. The side effects of long-term therapy are many (Table 13-6) and potential hematologic benefit must be weighed against undesirable manifestations.

*Estrogens* may relieve the anemia in postmenopausal patients with metastatic carcinoma of the breast, and in patients with metastatic carcinoma of the prostate. *Androgens* may likewise be used in metastatic carcinoma of the breast, when estrogens fail. Oxymetholone, testosterone enanthate, and other congeners of androgenic hormones have been used to stimulate erythropoiesis in the bone-marrow failure of aplastic anemia, congenital hypoplastic anemia of children, myelofibrosis, paroxysmal nocturnal hemoglobinuria, and other conditions.<sup>63,110,283</sup> Even though their major action is via eryth-

ropoietin, and erythropoietin excretion is already high in such patients, useful therapeutic successes have been claimed. The underlying disorders are not improved except, perhaps, in aplastic anemia.

### Chemotherapy and Irradiation

*Chemotherapy* can relieve the anemia in leukemia, Hodgkin's disease, and related conditions when such treatment influences the disorder causing the anemia. Thus, the administration of busulfan in chronic myelocytic leukemia, adrenal glucocorticoid hormones and metabolic antagonists in acute leukemias, and nitrogen mustard, or other alkylating agents together with other compounds, in Hodgkin's disease (page 1559) may all bring about disappearance of anemia as well as relief of other manifestations of the disease in question. In other conditions, such as the anemia associated with metastatic malignant tumors of the bone marrow, chemotherapy is less often effective but may have a dramatic effect. Details of the treatment of these and related disorders are discussed separately in the specific chapters dealing with these diseases.

*Irradiation* therapy from external sources such as  $^{60}\text{Co}$ , roentgen therapy, the linear accelerator, or internal irradiation with radioactive phosphorus may be used to advantage in selected anemic patients with lymphoma,

leukemia, or sometimes metastatic carcinoma. In these subjects, judicious treatment can bring about temporary or even long-term remissions, and thereby control the anemia. On the other hand, too vigorous treatment can add problems of drug- or radiation-induced bone marrow failure.

## Anemia in Pregnancy

Anemia in pregnancy is a multifaceted subject. It must first be appreciated that, beginning in the sixth week of pregnancy, the plasma volume increases disproportionately to the red cell mass. The plasma volume reaches a peak value at 24 weeks,<sup>201</sup> or later.<sup>202</sup> On the average, the maximal value is 43% greater in pregnant women than in nonpregnant women<sup>198</sup> (Table 13-7). Thus, even if the red cell mass did not change, a "dilutional anemia" would result. Indeed, a reduction in the hematocrit and hemoglobin concentration is evident by the sixth or eighth week of normal pregnancy<sup>165,203,214</sup> and progresses until the sixteenth or twenty-second week when a new equilibrium is established.<sup>198,202</sup> These values usually stabilize, with the hematocrit at 0.32 to 0.34 l/l and the hemoglobin at 11 g/dl. Red cells remain normochromic and normocytic unless deficiency of iron or folate supervenes. When the hemoglobin concentration is less than 10.4 g/dl, a true reduction in red cell mass

\* Collected data from reference 173. Only direct measurements of plasma volume or red cell mass are included. Inferred values of one computed from measurement of the other, are not included.

*n* refers to the number of subjects studied. SD to standard deviation.

is likely to be present, but, because of variations in the hydremia, a fixed dividing line between the normal and abnormal is more difficult to place in pregnancy than under other circumstances.<sup>178</sup> The relationship between the hematocrit of venous blood and the hematocrit of the body as a whole is probably unchanged in pregnancy,<sup>213,217</sup> although some reports indicate that it is variable.<sup>32,211,228</sup>

Masked by the dilutional effect, there is an actual increase of about 17 to 25% in the red cell mass during pregnancy.<sup>173,193,214</sup> (Table 13-7). A greater increase in red cell mass occurs in normal pregnancy if iron supplementation is taken.<sup>178</sup> Ferrokinetic studies have shown accelerated erythropoiesis during pregnancy, supporting the concept of an actual increase in red cell mass.<sup>215,218</sup>

Data regarding a reduction in plasma volume and an increase in hemoglobin concentration during the final six weeks of normal pregnancy are conflicting.<sup>173,178</sup> Measurements of plasma volume made in late pregnancy with the patient supine, as contrasted to those made with the patient in the decubitus position, are subject to error attributed to interference with the circulation imposed by the gravid uterus.<sup>173</sup> With this in mind, conflicting reports regarding changes in plasma volume near term may only represent variations within the error of measurement, or random occurrences.<sup>208,209,214</sup>

The mechanisms underlying these changes in blood volume and red cell mass are obscure. An increase in urinary and plasma

erythropoietin in the last two trimesters has been documented.<sup>201</sup> Plasma erythropoietin has been reported to be 30 to 35% greater in pregnant women near term, than in nonpregnant women, and it decreases promptly after delivery.<sup>205</sup> Perhaps of significance are the observations made in the pregnant mouse, whose changes in blood volume and red cell mass parallel those of the human.<sup>192</sup> Erythropoietic activity in serum is greater in the pregnant than in the nonpregnant mouse.<sup>191</sup> Human placenta lactogen stimulates erythropoiesis in the mouse,<sup>192,193</sup> but it is not known whether that hormone is responsible for the increased red cell mass in the pregnant woman.

In the puerperium, the blood volume returns to normal within one to three weeks,<sup>181,202,228</sup> partly reflecting blood loss at delivery<sup>218</sup> and partly the return of the plasma volume to normal.<sup>178</sup>

Iron deficiency not infrequently complicates the picture<sup>178</sup> (Chapter 17). Limited iron reserves even before pregnancy are commonplace<sup>210,216,223</sup> and the additional iron requirements of pregnancy impose a negative iron balance<sup>167,210,229</sup> unless supplemental iron is provided.<sup>178</sup> Frank iron deficiency is a common cause for anemia in pregnancy. The usual criteria for diagnosis apply (Chapters 16 and 17), including, in particular, reduction in the serum iron concentration to less than 60 µg/100 ml (10.7 µmol/l), occurring together with a transferrin saturation of less than 16% and, in the more severe cases, hypochromia of the red cells and a

reduction in the MCHC. However, even in apparently healthy women, during pregnancy there is a progressive decline in the serum iron, and an increase in the serum total iron-binding capacity and in the erythrocytic free protoporphyrin.<sup>178,180</sup> Findings that are associated with iron deficiency.<sup>142,99</sup> Dietary supplementation with 78 mg of elemental ferrous iron daily during pregnancy increased the hematocrit, hemoglobin concentration, and red cell mass during pregnancy, these values rising to nearly twice those found in similar, apparently healthy women who did not receive the supplement.<sup>178</sup> At term, the mean hemoglobin concentration was 12.4 g/dl in those who received the iron supplement, and 10.9 g/dl in those not receiving it.<sup>178</sup> In Bantu women whose diet is habitually high in iron, a significant change in serum iron does not occur and iron-deficiency anemia does not develop during pregnancy.<sup>185</sup>

*Macrocytic anemia of pregnancy* is often megaloblastic and in most cases is due to deficiency of folic acid.<sup>168,183,186,196,199,200,225</sup> When it occurs, megaloblastic anemia is found most often in the third trimester, or shortly after delivery.<sup>183,221</sup> Folate requirements are higher during pregnancy, and the diets of many pregnant patients are insufficient to meet the increased need.<sup>172,177</sup> Although folate deficiency occurs most often in economically deprived patients, this consequence of poor eating habits is not confined to the poor.<sup>174,177,183,186,221</sup> In pregnant adolescents in particular, the diet may prove to provide an inadequate source of folate, regardless of the economic class.<sup>177</sup> In uncomplicated pregnancies, the gastrointestinal absorption of food folate (polyglutamate) and of folic acid (monoglutamate) is normal.<sup>207</sup> Folate deficiency in pregnancy is relatively common, although its frequency depends upon the population studied. Reports indicate that it varies from 2 to 3% up to about 50% of pregnant patients.<sup>174,190,200,221</sup> Not all patients in whom the serum concentration of folate is low will develop megaloblastic anemia. Of those who do, frequently the serum folate concentration was low earlier in pregnancy.<sup>221</sup> Dietary supplementation with

about 0.3 mg of folic acid daily during pregnancy will reduce the occurrence of megaloblastic anemia to about 0.7% of all pregnant women.<sup>190,221,231</sup> whereas a supplement of only 0.1 to 0.2 mg daily is not adequate to maintain serum folic acid concentration at normal levels.<sup>168,230</sup> A supplement of 0.45 mg daily results in supranormal values for serum folate,<sup>230,231</sup> but, even with this high a supplement, megaloblastic anemia may occur in an occasional pregnant patient in whom the course is complicated by urinary tract infection or by hemorrhage.<sup>231</sup> Nevertheless, since true pernicious anemia due to lack of intrinsic factor and vitamin B<sub>12</sub> does occur in pregnant patients,<sup>204</sup> the considerations mentioned elsewhere (page 553), regarding masking of pernicious anemia with folate doses of 0.40 mg/day or more, apply. Accordingly, daily supplements of 0.3 mg of folic acid, but not more, are generally prescribed in pregnancy.

A positive association between bacteriuria and folate deficiency has been found in pregnant patients.<sup>204</sup> In experimental systems, infection may induce folate-deficient megaloblastic anemia.<sup>208</sup> Other complications of pregnancy such as increased incidence of abruptio placentae, uterine bleeding, prematurity, reduced birth weight, and fetal malformations<sup>175,188,189,195,204,225</sup> have been attributed to folate deficiency, but some large clinical studies do not confirm such a relationship.<sup>177,219,224,231</sup>

Malabsorption (Chapter 14) may cause, or be associated with, megaloblastic anemia of pregnancy, even in nontropical areas.<sup>196</sup>

Rarely, the folate-deficient pregnant patient may present with *erythroblastopenia* and a bone marrow appearance so closely simulating acute leukemia, because of the predominance of granulocyte precursors, that even hematologists may diagnose it as such. In one case, the findings suggesting leukemia were so convincing that 6-mercaptopurine was prescribed for four months.<sup>197</sup> If one is aware that confusion between these diagnoses has occurred before, and applies the strict criteria given elsewhere in this book (Chapter 41), difficulty should be avoided. Extra effort

is always appropriate to exclude the possibility of a treatable, although seemingly unlikely diagnosis, when the alternative is an incurable disease.

Pregnant patients are, of course, also liable to the same diseases that afflict other women. Some chronic anemias present special hazards to the pregnant patient. Sick cell disease<sup>181</sup> and other conditions in this category are considered elsewhere in this book.

## Features of Anemia Unique to Infants and Children

The first days and months of life require special hematologic consideration for several reasons. (1) certain diseases are unique to the newborn; (2) normal values differ from those of older children and adults, and significant changes occur in the first week after delivery; (3) the enzyme content and activity of the circulating red cells, and their content of fetal hemoglobin, are not identical with those found later in life; (4) the responsiveness of the hematopoietic system of the newborn and of infants and children is not the same as in adults; (5) nutritional factors may have a great effect upon the hematopoietic system; (6) growth imposes increased requirements for iron and other factors required for erythropoiesis; and (7) many congenital and hereditary disorders first make their appearance early in life.

Several special features characterize the erythrocytes of the newborn. Erythropoiesis is accelerated as compared with the adult. This is reflected in reticulocytosis, macrocytosis, and the presence of nucleated red cells in the circulation. Erythrocytes of the newborn remain in the circulation for an average of 85 to 91 days, as compared with 120 to 127 days in the adult.<sup>263,289</sup>

### Red Cell Enzymes

In the relatively immature erythrocytes of the newborn, the activity of certain enzymes is increased.<sup>293</sup> These enzymes include hexo-  
glucose-6-phosphate dehydrogenase (G6PD), 6-phosphogluconic acid dehydro-

genase, aldolase, phosphoglyceric acid kinase, pyruvate kinase, and lactate dehydrogenase (LDH).<sup>276,286</sup> The activity of G6PD is greater at birth than in later life, but decreases during the third to ninth weeks of life. It rises again in the subsequent eight weeks.<sup>268</sup> On the other hand, the activity of certain other enzymes is decreased at first, and only later attains the rates found in adults. Thus, phosphofructokinase<sup>276</sup> and acetylcholinesterase activity (AChE) are lower at birth than in the red cells of adults. The latter decreases even further and then increases in subsequent weeks, to reach, by the fourth month of life, values that are found in adults.<sup>268</sup> The low activity of NADP-dependent *methemoglobin reductase* (diaphorase) plays a role in the infant's increased susceptibility to the development of methemoglobinemia (page 1011). Carbonic anhydrase, catalase, and glyoxalase are also low in the erythrocytes of the newborn.

*Instability of ATP* is a feature that is even more marked in the red cells of the premature infant than in infants born at term.<sup>277</sup> The mechanical fragility of red corpuscles of the newborn is increased. There also are differences in the antigenic components, particularly of the Ii blood group system (page 458).

After the first few days of life, the rate of synthesis of hemoglobin slows down greatly and does not accelerate again until the infant reaches the age of 1½ to 2½ months.<sup>263,268</sup> (page 56).

### Hematopoietic Equilibrium

The hematopoietic equilibrium of the newborn and infant is less stable than that at later ages. As a result, the effect of any given stimulus, such as infection, may differ not only quantitatively, but also qualitatively. Leukocytosis may be striking, and myelocytes or even myeloblasts may be found in the circulation instead of a slight or moderate "shift to the left" which may occur in adults in similar circumstances. Anemia may be more profound, and nucleated red cells may appear in the circulation, whereas only polychromatophilia and reticulocytosis would de-

velop in an adult. Lymphocytosis develops frequently and to a more striking degree, and the spleen, lymph nodes, and liver become enlarged more readily than in adults.

These differences in the response of the hematopoietic system explain some of the observations which led to the term "anemia pseudoleukemica infantum," introduced by von Jaksch<sup>290</sup> to describe certain anemic conditions in infants. No doubt, this represented the consequence of a variety of factors including nutritional deficiencies, gastrointestinal disturbances, syphilis, tuberculosis and a number of other infections, iron deficiency, and even thalassemia. The term was applied to patients under three years of age with splenomegaly, hepatomegaly, lymphadenopathy, and anemia with marked anisocytosis, poikilocytosis, erythroblasts and macro-normoblasts in the circulation, extreme leukocytosis, and relative lymphocytosis. This is mentioned to emphasize that, when compared with the blood of adults, the morphologic features of the blood in infants may be more complex or bizarre in response to relatively commonplace disorders.

### Hereditary and Prenatal Factors

*Genetic constitution* as regards the hematopoietic system of the fetus may, both directly and indirectly, govern the fetus' survival. Certain genetic determinants, by direct effect, may be lethal. Thus, homozygosity for *alpha thalassemia* markedly restricts the capacity to synthesize alpha chains of hemoglobin. When completely expressed, this precludes synthesis of even fetal hemoglobin (Chapter 26) and results in *fetal hydrops*. Homozygosity for the methemoglobins (Hb M) presumably would be a lethal anomaly (Chapter 31), for it would preclude reversible binding of oxygen by hemoglobin. Only the heterozygous forms have been identified in living persons. The same also may be true for hereditary telangiectasia (page 1144).

Inheritance acts by an indirect mechanism in the *isoimmune diseases*. For example, in *erythroblastosis fetalis* resulting from Rh antigen incompatibility between mother and

fetus, the adverse consequences result from the antibodies produced by the mother that escape into the fetal circulation, there acting against the erythrocytes<sup>291</sup> (Chapter 27). The fate of the fetus depends upon the quantity and timing of the antibody production. Other, less serious forms of isoimmune hemolytic anemia operate similarly.

Factors concerned with the fetal environment and its unique relationship to the maternal circulation and, sometimes, to a twin pregnancy, may also act to produce anemia in ways which do not occur in adults. Such causes for anemia in the newborn are listed in Tables 13-8 and 13-9. These are less likely to be lethal than the aforementioned genetic and isoimmune disorders, provided they are recognized at once and treated. As in adults, the causes may be conveniently grouped into those due to hemorrhage, hemolysis, and erythroid hypoplasia or underproduction.

Constitutional aplastic anemias are discussed in Chapter 56 (page 1770).

### Hemorrhage

The general considerations regarding anemia due to acute and chronic blood loss mentioned earlier in this chapter apply to the newborn. Special attention must be given to the small blood volume of the infant. In a newborn, the blood volume averages 80.4 ml/kg.<sup>275</sup> The loss of 30 to 50 ml of whole blood will produce pallor, anemia, and severe distress. Loss of a greater quantity of blood may produce shock. Similarly, small losses (by absolute measure) of fluid may result in significant dehydration and alter the hematocrit accordingly; parenteral administration of blood or fluids will likewise have a relatively greater effect than in adults. The causes of hemorrhagic anemia in the newborn are given in Table 13-9.

*Feto-maternal hemorrhage*<sup>254,280</sup> of more than 40 ml is sufficient to produce an anemic infant. This occurs in nearly 1% of pregnancies.<sup>255</sup> To a lesser degree, *feto-maternal transfusion* occurs in about half of all pregnancies.<sup>255-294,295</sup> However, in only 8 or 9% does the amount exceed 0.5 ml.<sup>235</sup> The presence of fetal erythrocytes in the maternal circulation can be demonstrated by the technique of Kleihauer et al.<sup>270</sup> On a blood film prepared from the mother, hemoglobin A is eluted from the red cells at an acid pH, whereas fetal hemoglobin remains. The latter

may be seen on microscopic examination of the stained blood film.<sup>285</sup> The possibility of other conditions resulting in an increase in hemoglobin F in maternal red cells must be excluded for this test to be applicable. Differential agglutination is a less sensitive approach to the detection of fetal erythrocytes in the maternal circulation,<sup>254,265</sup> and chemical estimation of the hemoglobin F content in maternal blood will only suffice to detect the largest feto-maternal hemorrhages. Repeated fetal blood loss by this mechanism over some period of time<sup>291</sup> can result in iron-deficiency anemia in the newborn.<sup>280,282</sup>

The "*twin transfusion syndrome*,"—transfusion from one fetus to another via an arterio-venous communication or other shunt, in a monozygotic twin pregnancy—results in anemia in one and polycythemia in the other twin.<sup>257,274</sup> It is not rare, having been found in 19 of 130 monozygotic twin pregnancies.<sup>281</sup> The effects may be severe. If a still-birth does not result, listlessness or shock is present at birth in the anemic member,<sup>291</sup> and hypertension, cardiomegaly, hepatosplenomegaly, polyhydramnios, and later congestive heart failure occur in the plethoric member. Death may occur in the neonatal period unless treatment is given promptly.<sup>281</sup> The syndrome should be suspected if the hemoglobin concentration in twins of the same sex differs by more than 3.3 g/dl at birth.<sup>281</sup> If such difference is found, the placenta should be examined for an arterio-venous communication, or a laceration.

Hemorrhage from rupture or tear of the *placenta or umbilical vessels* has been secondary only to hemolytic disease as a cause of anemia in the newborn.<sup>269</sup> Now, with the decline in frequency of Rh-induced hemolytic disease (Chapter 27) in the newborn, hemorrhage from rupture or tear will become even more important. The infant may be listless, pale, or in shock. The diagnosis is made on inspection of the umbilical cord and placenta.

### Hemolytic Disease

In the newborn, hemolytic disease is most often of the isoimmune type (Chapter 27)

although most of the inherited and some of the acquired forms of hemolytic disease also occur (Table 13-8).

In contrast to the characteristic findings in the adult with hemolytic disease, the infant is usually free of jaundice at birth, despite accelerated red cell destruction. In the next few days of life, jaundice appears and, compared with the findings in adults, it increases out of proportion to the rate of destruction of red cells.

There are unique features of the bilirubin catabolism in the fetus and newborn which affect the clinical presentation and consequences of hemolytic disease in the fetus and in the newborn. The liver is deficient in *glucuronyl transferase* activity until the infant is a few days old.<sup>272</sup> As a result, the normal conversion of bilirubin to the diglucuronide (Chapter 5) is impaired and excretion of the catabolic products of hemoglobin via the normal biliary pathway is reduced. During intrauterine life, the deficiency of glucuronyl transferase does not present a serious problem, since bilirubin readily traverses the placenta.<sup>286</sup> It is then metabolized and excreted by the mother so effectively that the newborn is free of jaundice even when there is hemolytic disease with accelerated destruction of red cells. The situation changes abruptly at birth with the loss of the maternal pathway. Bilirubin accumulates in the plasma, bound to albumin. For every gram of hemoglobin catabolized, about 35 mg of bilirubin result. This quantity is distributed in the smaller extracellular fluid space of the infant, resulting in a greater increment in bilirubin concentration than would occur in the adult. Until bilirubin glucuronide excretion is established, the bilirubin concentration rises in the serum. Degradation of the diglucuronide by intestinal  $\beta$ -glucuronidase activity in the intestine allows some bilirubin to be reabsorbed. The combination of these factors causes the serum bilirubin concentration to rise and clinical jaundice to worsen more quickly than would be expected under parallel circumstances of hemolytic disease in the adult. If the serum concentration of bilirubin exceeds 20 mg/dl, there is a danger of

kernicterus<sup>264</sup> and its disastrous consequences.<sup>265</sup>

*Genetically determined hemolytic diseases* may be symptomatic in the newborn (Table 13-8), although sickle cell disease, thalassemia, and hereditary spherocytosis usually are not. However, when a hemolytic anemia with spherocytic red cells is present at birth, hereditary spherocytosis must be considered as well as isoimmune disease (ABO incompatibility) (Chapters 21 and 27). It must be remembered that in about one sixth of the patients with hereditary spherocytosis, the disorder cannot be demonstrated in the parents even though it is believed to be transmitted as an autosomal dominant. Hence, the differentiation of genetically determined disorders may not always be simple.

*Drug-induced hemolytic disease* with hyperbilirubinemia has been reported in infants, particularly premature, who had been given 5 or more milligrams of a water-soluble vitamin K preparation,<sup>250</sup> intended as prophylaxis against hemorrhagic disease of the newborn. The adverse effect can be avoided if the dose is not greater than 1 mg.<sup>251</sup> *Glucose-6-phosphate dehydrogenase deficiency* may be associated with hyperbilirubinemia in some infants<sup>290</sup> or with drug-induced hemolytic disease. The latter may even result from drug exposure of the infant when in utero.<sup>292</sup> These disorders are fully discussed elsewhere in this volume.

## Nutritional Considerations in Anemia in Infants and Children

The nutritional requirements of the infant and child are especially important in the light of the rapid growth which must occur. Iron reserves are influenced by the timing of the tying of the umbilical cord. If the cord is tied too early, the infant will be deprived of additional red cells from the placenta, which would provide not only additional blood volume but also additional iron reserve. The hemoglobin concentration at birth is higher than will be found later. Part of this excess

will contribute to iron reserve. After birth, iron requirements are provided by the diet which, if confined to milk, will be insufficient. These topics are discussed in detail in Chapter 17 (page 645), where the problems of the premature infant are also considered. Deficiencies of folic acid and protein also play important roles in anemia in childhood, as discussed in Chapter 14 (page 578).

It should be clear from the above that the differentiation of the causes of anemia in the newborn requires especially careful consideration of the family history, maternal health, and obstetric history. Infants, of course, cannot complain of weakness nor can they relate symptoms to direct attention to a specific organ system. The mother's observations are often helpful, but may be inadequate or misleading. Therefore, more than ordinary reliance must be placed upon careful observation and physical examination. With the exception of the factors already discussed, including the differences in normal values for the various age groups, the results of laboratory tests and their interpretation are as they would be in the case of adults.

### *Macrocytosis and Macrocytic Anemias*

Significance of Macrocytosis  
Defective DNA Synthesis  
Accelerated Erythropoiesis  
Increased Membrane Surface Area  
Non-megaloblastic, Macrocytic Anemia  
Megaloblastic Anemia  
Laboratory Manifestations  
Disorders Associated with Megaloblastic Anemia  
Laboratory Tests Useful in Differential Diagnosis  
Diagnostic Approach to the Patient  
Management

THE macrocytic anemias are characterized by an increase in the average size of the erythrocyte. Usually the amount of hemoglobin in each cell is increased in proportion to size. Thus, in typical macrocytic anemia, the mean corpuscular volume (MCV) and mean corpuscular hemoglobin (MCH) are increased, and the mean corpuscular hemoglobin concentration (MCHC) is normal (Fig. 14-1).

Macrocytosis may also be detected by examination of the blood smear, since the average red cell diameter is increased; however, considerable patience is required to achieve precision in the microscopic detection of macrocytosis. Often, the change is accompanied by anisocytosis, which complicates the problem of estimating the average size. Furthermore, a change in diameter may not be apparent until the observer has examined many normal smears with the same microscope. Even experienced hematologists

should acquire the habit of comparing the abnormal smear with reference smears of normal blood. Otherwise, minimal to moderate deviations from normal may be overlooked.

In macrocytic anemia, most macrocytes are thicker than normal. Unless there is complicating iron deficiency the cells are well filled with hemoglobin. With the microscope, the increased thickness is perceived as a loss of central pallor. Because of these changes, the term "hyperchromic" was applied to the macrocytic anemias. This misleading term should be avoided because it suggests that the cellular concentration of hemoglobin is increased. In macrocytic anemia, as previously noted, hemoglobin content (MCH) is increased only in proportion to size; concentration, as measured by the MCHC, remains within normal limits.

### **Significance of Macrocytosis (Table 14-1)**

#### **Defective Deoxyribonucleic Acid (DNA) Synthesis**

The megaloblastic anemias are a group of disorders in which DNA synthesis is defective.<sup>9,15</sup> It has been proposed that this biochemical abnormality leads to a state of unbalanced cell growth, in which ribonucleic acid (RNA) and protein syntheses continue while DNA synthesis is retarded.<sup>1,15</sup> Thus, cytoplasmic components, especially hemoglo-

Fig 14-1. Erythrocyte indices in 28 patients with untreated or relapsed pernicious anemia. The dashed lines enclose the 95% confidence limits in normal subjects. (From Hallberg,<sup>25</sup> courtesy of the author and Scandinavian Journal of Clinical and Laboratory Investigation.)

bin, are synthesized in excessive amounts during the delay between cell division. An enlarged cell is the final end-product of such a process.

### Accelerated Erythropoiesis

Macrocytosis frequently follows intense, erythropoietin-mediated stimulation of red cell production, such as may be induced by blood loss or hemolysis. At least three mechanisms appear to account for the increased cell size. First, the reticulocyte count increases, and normal circulating reticulocytes are about 20% larger than mature red cells.<sup>8,16</sup> Second, there is premature release of bone marrow reticulocytes ("shift" reticulocytes), which are larger and contain more RNA than normal circulating reticulocytes.<sup>6</sup> Finally, with intense stimulation, an erythroblast cell division may be skipped, a phenomenon that results in a macroreticulocyte that is approximately twice normal size.<sup>3,11,13</sup> The importance of the last mechanism in man has been questioned.<sup>6</sup> As macroreticulocytes cir-

culate, they lose water and hemoglobin intravascularly, possibly by cell fragmentation, until near normal size has been reached.<sup>5</sup>

### Increased Membrane Surface Area

In patients with liver disease (Chapter 19), a significant increase in cell volume results from one of the two mechanisms described above.<sup>7</sup> In liver disease, however, "thin macrocytes," which are defined as cells with an increased surface area ("macroplania"<sup>14</sup>) but without a corresponding increase in volume, also may be observed.<sup>2</sup> On blood smear, "thin macrocytes" are characterized by an increased diameter and a visibly enlarged area of central pallor. The characteristic "target cell" of liver disease is a thin macrocyte. Since the volume of such cells is normal, their presence has no effect on the erythrocyte indices.

The increased surface area of thin macrocytes is the consequence of excessive membrane lipids, especially cholesterol<sup>4,14</sup> but also phospholipids.<sup>10</sup> These alterations are reversible upon incubation in normal plasma and, conversely, can be induced in normal cells by incubating them in plasma from jaundiced subjects. The responsible plasma components probably are bile salts, which both inhibit cholesterol esterification and increase the rate of erythrocyte cholesterol uptake<sup>4</sup> (see Chapter 3).

Thin macrocytes with increased membrane lipid may also be observed after splenectomy. Apparently, membrane lipids normally are lost during the maturation of reticulocytes in the spleen<sup>12</sup>; in the absence of this organ, the lipid loss is of lesser magnitude.

## Non-megaloblastic Macrocytic Anemia

It is important to be aware of non-megaloblastic macrocytic anemias (Table 14-1, categories 2, 3, and 4) in order to avoid confusing them with the megaloblastic anemias. The non-megaloblastic anemias are only occasionally macrocytic; more often, they are normocytic. For that reason, the

**Table 14-1. Causes of Macrocytic Anemia**

- 1 Defective deoxyribonucleic acid (DNA) synthesis (the megaloblastic anemias—Table 14-3)

  - a Myxedema
  - b Hypoplastic anemia
  - c Acquired sideroblastic anemias
  - d Myelophthisic anemia

detailed discussion of these anemias is to be found in other sections of this book.

## Megaloblastic Anemia

### Laboratory Manifestations

#### The Blood

In the megaloblastic anemias, the degree of anemia ranges from levels barely compatible with life to levels indistinguishable from normal (Fig. 14-2). When symptoms of anemia are the presenting complaints the blood hemoglobin concentration usually is

Fig 14-2. Severity of the anemia as measured by the volume of packed red cells (VPRC), in untreated patients with pernicious anemia (Prepared from data of Cox<sup>21</sup>)

less than 7 or 8 g/dl. However, if the patient is examined because of other symptoms, such as an underlying or unrelated disease, or if neurologic manifestations predominate, the degree of anemia is likely to be less pronounced.

When not complicated by iron deficiency, the anemia is found to be macrocytic and normochromic (MCHC within normal limits) (Fig. 14-1). The increase in MCV is to a large extent directly proportional to the degree of anemia, but other factors, such as the number of immature red corpuscles, also are important.<sup>15</sup> When the anemia is slight or moderate in degree, values of 95 to 110 fl ( $\mu^3$ ) are common (normal 82 to 92 fl ( $\mu^3$ )); when it is more severe the mean corpuscular volume may be 110 to even 160 fl and generally is found to range between 110 and 130 fl. The values for MCH will be found generally to range from 33 to 38 pg (normal 27 to 31 pg) when the anemia is moderate, and from 33 to even 56 pg when it is more severe.

The total leukocyte count may be within the normal range or below it. When the anemia is mild to moderate, the leukocyte count usually is  $3.0$  to  $6.0 \times 10^9/l$ . With more severe degrees of anemia, even greater reduction in the number of leukocytes may be observed ( $1.0$  to  $3.0 \times 10^9/l$ ).<sup>23</sup> The leukopenia usually is the result of absolute neutropenia.

The platelets generally are reduced in number, particularly when the VPRC is lower than 0.25 l/l. The platelet count may then be less than  $100 \times 10^9/l$ .<sup>56</sup> Bizarre forms, including giant platelets, may be found; the bleeding time may be prolonged; the blood clot may retract poorly; and even purpura, as well as retinal hemorrhages, may occur.<sup>60</sup>

### Morphologic Characteristics

The two principal findings on blood smear are hypersegmentation of the granulocytes and macroovalocytosis of the erythrocytes (Fig. 14-3). The leukocyte changes are particularly noteworthy because they are among the first hematologic abnormalities to appear

Fig 14-3 Photomicrograph of blood smears from patients with pernicious anemia in relapse showing (above) the macrocytosis, anisocytosis, and poikilocytosis, and (below) a multisegmented neutrophilic leukocyte (Wright's stain,  $\times 1040$ )

as the megaloblastic state develops.<sup>40</sup> Normally, the nuclei of circulating, segmented neutrophils have less than five lobes. In megaloblastic anemia, segmentation is increased, and cells with six to even 10 or more nuclear lobes may be detected. Various measures have been proposed to quantitate the degree of hypersegmentation. The simplest screening technique is that of recording the number of segmented neutrophils with five or more lobes seen during the course of a 100-cell differential count. If more than three cells with five lobes, or even a single cell with six or more lobes, are observed, a presumptive diagnosis of hypersegmentation may be made. A "lobe average" may be determined by counting the number of lobes in the nuclei of 100 consecutive neutrophils and dividing by 100. Depending on the way in which a nuclear "lobe" is defined (see discussion in Chapter 6), the normal lobe average is  $3.17 \pm 0.25^{41}$  or  $2.03 \pm 0.39.^{54}$  An increase

in this value is one of the most sensitive indicators of the biochemical disorder that results in megaloblastic anemia.<sup>41</sup> Possibly even more sensitive is the calculation of the ratio of five-lobed to four-lobed granulocytes, which should be less than 0.17 in normal subjects.<sup>26</sup>

The main products of megaloblastic erythropoiesis are macrocytic erythrocytes with a distinctly oval shape. Such cells are well filled with hemoglobin and often the area of central pallor is reduced or absent. The oval shape may be particularly useful in distinguishing megaloblastic anemias from other causes of macrocytosis. The macroreticulocytes that characterize stimulated erythropoiesis tend to be round and distinctly blue or gray in Romanowsky stains. The thin macrocytes of liver disease usually are round, and, in addition, appear as target cells or as cells with increased areas of central pallor.

Although oval macrocytes tend to predominate, there may be considerable variation in the size (anisocytosis) (Fig. 14-4) and shape (poikilocytosis) of the erythrocytes. These changes are most marked when the anemia is pronounced. The most bizarre shapes may be seen: cells in the form of dumbbells, anvils, cocked bats, hand-mirrors, and so on. Many of these deformed erythrocytes are smaller in diameter than the cells of normal blood.

In patients with advanced anemia, a wide variety of red cell inclusions may be found. There may be many diffusely polychromatophilic cells and others that show punctate basophilia. The stippling may be fine or coarse. In occasional cells, Howell-Jolly bodies and acidophilic rings of various shapes (Cabot's rings) may be seen. In addition, orthochromic, polychromatophilic, or basophilic nucleated red cells may be found. The chromatin structure of the nuclei of these cells may be very fine so that they are readily recognized as megaloblasts (see below).

### Bone Marrow

The marrow is cellular and usually hyperplastic, with erythrocyte precursors predomi-

Fig 14-4 The variation in the diameters of the red corpuscles in a patient with pernicious anemia in relapse (continuous line) compared with the variation in health. The curves set out by the interrupted lines define the limits of normality as represented by  $\pm 3$  times the standard deviation of the mean diameter in the healthy adult. The degree of macrocytosis and microcytosis was estimated by counting the number of cells outside these boundaries. The skewness of the pernicious anemia curve is emphasized by comparison with the normal distribution curve (marked by crosses) for cells of this mean diameter. (From Price-Jones,<sup>40a</sup> courtesy of the author and Oxford University Press.)

nating. The characteristic *megaloblasts* are distinguished by their large size and, especially, by their delicate nuclear chromatin. The chromatin has been called "particulate" or "sieve-like," as distinguished from the normal denser chromatin of normoblasts, and resembles fine scroll work (Fig. 14-5, page 571, and Plate IX). This morphologic change may be detected at all stages of erythrocyte development. Thus, there are promegaloblasts and basophilic, polychromatophilic, and orthochromic megaloblasts. The cytoplasm of the very early stages is so deeply basophilic that it may be difficult to recognize these cells as erythrocyte precursors.

The identification of orthochromic megaloblasts is particularly useful in recognition of megaloblastic anemia because they differ so markedly from any cell found in normal marrow.<sup>41</sup> In the orthochromic megaloblast,

the abundant cytoplasm appears mature (pink), whereas the nucleus appears immature as the result of the megaloblastic change ("nuclear-cytoplasmic dissociation," "nuclear-cytoplasmic asynchrony"). An unusually large number of mitotic figures are to be found among the erythroid cells.

Associated with changes in the erythrocyte precursors is evidence of active and abnormal leukopoiesis. In addition to myeloid leukocytes of normal appearance, extraordinarily large (up to 20 or 30  $\mu$ m) leukocytes will be found. These monstrosities of cellular development may occur at any stage in the myeloid series, but they are particularly common among the metamyelocytes.<sup>33</sup> The nucleus of these so-called "giant metamyelocytes" is enlarged, both absolutely and in relation to the total cell size; it may be bizarre in shape and in chromatin structure or staining prop-

erties (Fig. 14-5). Occasionally small vacuoles are found in the cytoplasm. Giant metamyelocytes contain more than a diploid ( $2n$ ) amount of DNA and appear to be arrested in a premitotic stage of development.<sup>63</sup> It is therefore likely that they die within the marrow and are not precursors of the hypersegmented neutrophil.

In general, proliferation of megakaryocytes is less disturbed than that of either of the other two cell lines; however, when megaloblastic change is severe, megakaryocytes may

be reduced in number and there may be abnormalities of nuclear chromatin.<sup>30</sup> Furthermore, DNA synthesis may be arrested.<sup>57</sup>

All of the above changes vary in intensity depending on the degree of the deficiency or metabolic defect leading to the anemia. When deficiency is mild and there is little anemia, unequivocal megaloblasts in the marrow may be difficult to find. The terms "intermediate megaloblast" and "transitional megaloblast" have been used to describe the minimal alterations found in erythroid precursors under

Fig. 14-5. Photomicrograph of the bone marrow of a patient with pernicious anemia in relapse. Megaloblasts in various stages of development are shown. Nucleoli are visible in some of these cells. The typical chromatin pattern should be noted. In the upper two photographs, "giant metamyelocytes" are also seen (Wright's stain  $\times 1040$ ).

such circumstances. This terminology has been criticized; possibly the phrase "early megaloblastic changes" is preferable.<sup>23</sup>

### *Erythrocyte Kinetics and the Metabolism of Iron and Bilirubin*

Erythrocyte survival in megaloblastic anemia generally is considered to be moderately reduced, although relatively few direct measurements have been made. In a total of five patients with pernicious anemia studied by the Ashby technique,<sup>50,59</sup> the survival of erythrocytes ranged from 27 to 75 days (normal, 120 days). Chromium half-disappearance times ( $T_{1/2}$  Cr) were found to be 16 to 21 days (normal, about 32 days) in three patients.<sup>11,43</sup> For the most part the excessive red cell destruction appears to result from a defect in the red cell itself. However, there also is evidence that normal cells transfused into patients with pernicious anemia are destroyed randomly at an increased rate.<sup>36</sup> The extracorporeal hemolytic factor suggested by these studies could be demonstrated *in vitro* in plasma, but it was not characterized further. It disappeared between three and nine days after vitamin B<sub>12</sub> was given. That at least part of the erythrocyte destruction occurs intravascularly is suggested by the observation that, in serum, haptoglobins are absent and methemalbumin may be present.<sup>83,95</sup>

The serum iron concentration is moderately increased unless there is complicating iron deficiency.<sup>23</sup> Bone marrow sideroblasts and reticuloendothelial iron stores also tend to be increased. The plasma total iron-binding capacity may be slightly reduced. Ferrokinetic studies (Table 14-2) have demonstrated a threefold increase in the plasma iron-transport rate. However, red cell utilization is markedly reduced, so that erythrocyte iron turnover is about normal. These kinetic data reflect ineffective erythropoiesis (Chapter 13).<sup>31,52</sup> The measures of "total" erythropoiesis, such as the plasma iron-transport rate and the degree of red cell hyperplasia, are increased. In contrast, measures of "effective" erythropoiesis, such as the erythrocyte iron-

**Table 14-2. Ferrokinetic Studies in Megaloblastic Anemia<sup>32</sup>**

	Normal Subjects	Patients with Pernicious Anemia
Plasma Fe ( $\mu$ g/dl)	105	152
Iron clearance ( $T_{1/2}$ minutes)	86	46
Plasma iron transport (mg/day/dl)	0.7	2.4
Red cell iron utilization (%)	80	28
Erythrocyte iron turnover (mg/day/dl)	0.56	0.62

Values are means of measurements in 107 normal subjects and in 27 patients with pernicious anemia.

turnover rate and the reticulocyte count, are not increased.

Additional evidence for ineffective erythropoiesis has been derived from the study of bile-pigment production. The daily excretion of urobilinogen greatly exceeds that which can be accounted for on the basis of destruction of circulating red cells.<sup>31</sup> Furthermore, there is a dramatic increase in the "early-labeled" fraction of bile pigments<sup>49</sup> (Chapter 5). These observations indicate that the probable source of the excessive bile pigment in megaloblastic anemia is destruction of erythrocyte precursors within the bone marrow.

As a result of the increased production of bile pigment, slight unconjugated ("indirect") hyperbilirubinemia may be observed, although normal values are common and values exceeding 2.0 mg/dl are unusual. Of 20 patients with pernicious anemia reported by Schilling and Harris the serum bilirubin was less than 1.0 mg/dl in 11, 1.0 to 1.5 in eight, and 2.2 in one.<sup>58</sup> These values were compared with previous reports indicating that 103 of a total of 126 patients had increased serum bilirubin concentrations. Schilling and Harris suggested that, as the result of earlier diagnosis and the availability of effective treatment, less severe disturbances in bilirubin metabolism were seen than had previously been observed.

### Serum Lactate Dehydrogenase and Other Enzymes

Lactate dehydrogenase (LDH) activity tends to be greatly increased in patients with megaloblastic anemia. In one series of 16 patients, the mean value was 3800 units/ml (normal mean 260 u/ml).<sup>21</sup> Values exceeding 10,000 u/ml have been reported. The magnitude of the increase is related to the degree of anemia; a linear relation between the logarithm of serum LDH activity and hemoglobin concentration was found in one series.<sup>29</sup> Serum LDH also may be increased in hemolytic anemia, but usually to a lesser degree than in megaloblastic anemia (Fig. 14-6).

Of the five common isoenzymes of LDH, the two which migrate fastest on electrophoresis (LDH-1 and LDH-2) are the ones that account for the increase in megaloblastic anemia.<sup>64</sup> LDH-1 activity exceeds that of LDH-2, whereas the converse is true in hemolytic anemia. Accurate electrophoretic isoenzyme quantitation may not always be available, but a relatively simple method based on chloroform inhibition can also distinguish between the pattern in hemolytic anemia and that in megaloblastic anemia.<sup>64</sup> In megaloblastic anemia, the source of the serum enzyme is thought to be the cells destroyed by ineffective erythropoiesis in the marrow. With specific therapy, serum LDH levels return to normal within one to two weeks.

A variety of other red cell enzymes may be found in the serum in increased amounts.<sup>28,39</sup> Malate dehydrogenase, 6-phosphogluconate dehydrogenase, and  $\alpha$ -hydroxybutyrate dehydrogenase are increased to about the same extent as LDH; aldolase, phosphohexose isomerase, and isocitrate dehydrogenase are increased less consistently and to a lesser degree. Serum alkaline phosphatase activity is decreased in patients with pernicious anemia<sup>25</sup> as is serum and red cell cholinesterase.<sup>51</sup>

### Changes in Epithelium

In a variety of epithelial tissues, morphologic alterations that somewhat resemble the

Fig. 14-6 Serum lactate dehydrogenase activity in megaloblastic anemia, compared with iron-deficiency and hemolytic anemias. The dashed line indicates the upper limit of normal. (From Emerson and Wilkinson,<sup>29</sup> courtesy of the authors and Blackwell Scientific Publications.)

changes in marrow red cell precursors may be observed. The cells and their nuclei are abnormally large, nuclear chromatin is less coarse than normal, and multiple nuclei may be found. Such abnormalities may be in cells from the buccal,<sup>23</sup> gastric,<sup>34</sup> and vaginal mucosae<sup>34,48</sup> (Fig. 15-6, page 617).

### Cytogenetics

A variety of chromosomal abnormalities have been described in marrow cells from patients with megaloblastic anemia.<sup>37,44,45,46</sup> Individual chromosomes may be elongated and there is an increased frequency of randomly distributed gaps and breaks. Separation or spreading of the centromere has been observed.<sup>37</sup> Most investigators have reported a normal diploid number of chromosomes, but some have observed hypodiploidy.<sup>45</sup> The chromosomal abnormalities disappear promptly with effective treatment.<sup>44,46</sup>

### Miscellaneous Biochemical Findings

The serum potassium concentration may be slightly reduced; in one study, the values in 17 of 34 patients were less than 4.0 mEq/l, the lower limit of normal in that laboratory.<sup>47</sup>

Negative nitrogen balance is usually observed during relapse.<sup>42</sup> There may be slight excessive urinary excretion of taurine and other amino acids.<sup>33,62</sup> An increase in urinary hydroxyphenyl compounds, probably derived from tyrosine, has been observed.<sup>61</sup> Conversion of formate to serine by lymphocytes is inhibited.<sup>27</sup>

### Disorders Associated with Megaloblastic Anemia

In the great majority of patients, megaloblastic anemia is a consequence of deficiency of vitamin B<sub>12</sub> or folate, or both (Table 14-3). Nutritional aspects and the metabolism of these vitamins as well as their role in DNA

synthesis were discussed in Chapter 4. Rare causes of megaloblastic anemia include congenital disorders affecting DNA synthesis and certain drug-induced disorders (Table 14-3).

### Dietary Deficiency of Vitamin B<sub>12</sub>

Dietary deficiency of vitamin B<sub>12</sub> is very unusual because of the ubiquitous distribution of this vitamin and the extensive hepatic stores. Only strict vegetarians who avoid not only meat but also eggs and milk ("vegans") have been observed to develop vitamin B<sub>12</sub> deficiency because of dietary inadequacy.<sup>119,142</sup> Even in vegans, megaloblastic anemia is unusual; in one study, biochemical

**Table 14-3. Pathogenetic Classification of the Causes of Megaloblastic Anemia**

I Vitamin B <sub>12</sub> deficiency	1 Cirrhosis
A Dietary deficiency (rare)	2 Pregnancy
B Lack of Castle's intrinsic factor	3 Infancy
1 Pernicious anemia	4 Diseases associated with rapid cellular proliferation
a Congenital form	C Congenital folate malabsorption
b Adult form	D Drug-induced folate malabsorption
2 Gastrectomy	1 Anticonvulsants
a Total	2 Oral contraceptives
b Partial	E Extensive intestinal resection, jejunal resection
3 Ingestion of caustic materials	III Combined folate and vitamin B <sub>12</sub> deficiency
C Functionally abnormal intrinsic factor	A Tropical sprue
D Biologic competition	B Gluten sensitive enteropathy
1 Small-bowel bacterial overgrowth	IV Inherited disorders of DNA synthesis
a Small bowel diverticulosis	A Orotic aciduria
b Anastomoses and fistulae	B Lesch-Nyhan syndrome
c Blind loops and pouches	C Thiamin-responsive megaloblastic anemia
d Strictures	D Deficiency of enzymes required for folate metabolism
e Scleroderma	1 N <sup>5</sup> -methyl tetrahydrofolate transferase
f Achlorhydria	2 Formiminotransferase
2 Fish tapeworm disease	3 Dihydrofolate reductase
E Familial selective vitamin B <sub>12</sub> malabsorption (Imerslund's syndrome)	E Congenital megaloblastic anemia responsive to large doses of folate and vitamin B <sub>12</sub>
F Drug-induced vitamin B <sub>12</sub> malabsorption	V Drug induced disorders of DNA synthesis
G Chronic disease of the pancreas	A Folate antagonists (eg. methotrexate)
H Zollinger-Ellison syndrome	B Purine antagonists (eg. 6-mercaptopurine)
I Diseases especially affecting the ileum	C Pyrimidine antagonists (eg. cytosine arabinoside)
1 Ileal resection and bypass	VI Erythroleukemia
2 Regional enteritis	
II Folate deficiency	
A Dietary deficiency	
B Increased requirements	

evidence of vitamin B<sub>12</sub> deficiency was observed in only three of 26 vegans, none of whom was anemic.<sup>112</sup>

It follows that deficiency of vitamin B<sub>12</sub> is nearly always the result of defective absorption of the vitamin. This may occur because of lack of Castle's intrinsic factor (Chapter 4) or because of various disorders affecting the small intestine (Table 14-3).

### ***Pernicious Anemia***

The most common cause of intrinsic factor deficiency is pernicious anemia, which is discussed in Chapter 15.

### ***Gastrectomy***

Total gastrectomy removes all intrinsic factor-secreting cells, and vitamin B<sub>12</sub> deficiency will inevitably supervene if sufficient time elapses without parenteral vitamin therapy. The average duration from the time total gastrectomy was performed to onset of anemia was found to be five years (range two to 10 years).<sup>23</sup>

Megaloblastic anemia may also follow partial gastrectomy, even though this operation leaves intact some of the intrinsic factor-secreting parietal cells. Malabsorption of vitamin B<sub>12</sub> has been found in approximately 30 to 40% of subtotal gastrectomy subjects.<sup>117,129</sup> The absorptive defect is usually less severe than that occurring in pernicious anemia or after total gastrectomy.<sup>108,132</sup> Nevertheless, when follow-up was prolonged the incidence of megaloblastic anemia was as great as 18%.<sup>120</sup> The increased incidence with time following the operation<sup>141</sup> may possibly be due to gastritis developing in the gastric remnant.<sup>127,135</sup> Defective vitamin B<sub>12</sub> absorption was more common when the operation was performed for gastric ulcer than for duodenal ulcer.<sup>124,129</sup> Iron-deficiency anemia often complicates the picture and may obscure the megaloblastic changes. Although vitamin B<sub>12</sub> deficiency accounts for about 80% of the cases of megaloblastic anemia

following subtotal gastrectomy, folate deficiency also has been observed.<sup>120,133</sup> The pathogenesis of the latter is unknown.

### ***Ingested Corrosive Materials***

Megaloblastic anemia following destruction of gastric mucosa by ingested corrosive materials has rarely been reported.<sup>101</sup>

### ***Functionally Abnormal Intrinsic Factor***

In a report of a single patient, vitamin B<sub>12</sub> deficiency appeared to result from secretion of biologically inert intrinsic factor.<sup>125</sup> Intrinsic factor obtained from this patient was normal with respect to immunologic reactivity, chromatographic properties, and vitamin B<sub>12</sub> affinity; however, it could not correct the vitamin B<sub>12</sub> malabsorption of a gastrectomized subject nor could it stimulate vitamin B<sub>12</sub> uptake by homogenates of guinea pig ileum. The patient responded completely to parenteral administration of vitamin B<sub>12</sub>.

### ***Small Bowel Bacterial Overgrowth***<sup>111,114</sup>

The proximal small bowel in healthy subjects may be sterile or it may contain relatively low concentrations (usually less than 10<sup>3</sup> organisms/ml of contents) of gram-positive aerobes or facultative anaerobes, such as lactobacilli and enterococci along with some coliforms.<sup>114</sup> Normally, bacterial overgrowth in the small intestine is prevented to some extent by gastric acid secretion; however, the most important factor appears to be the mechanical cleansing action of normal peristalsis.<sup>111</sup> Any anatomic abnormality leading to stasis or recirculation of intestinal contents is likely to be accompanied by proliferation of microorganisms. The most common lesions that may have this effect are listed in Table 14-3 (I, D, 1, a-f). The bacterial population developing under such circumstances resembles that of the colon. Anaerobic lactobacilli and bacterioides tend to predominate, and coliforms and clostridia

may be found in high concentrations. The numbers of organisms may be large, up to  $10^{10}$ /ml.

The principal manifestations of the bacterial overgrowth syndrome are weight loss, megaloblastic anemia, steatorrhea, and diarrhea. The steatorrhea probably results from bacterial hydrolysis of conjugated bile salts to bile acids, which then are reabsorbed. By this mechanism, the concentration of intestinal bile salts becomes reduced below the critical level necessary for micelle formation, leading to malabsorption of fatty acids and monoglycerides.<sup>114,126</sup>

The megaloblastic anemia almost always results from vitamin B<sub>12</sub> deficiency. With rare exceptions,<sup>102</sup> folate absorption is not impaired; body folate stores are normal and may even be increased because of absorption of microbially synthesized folate.<sup>121</sup> Vitamin B<sub>12</sub> absorption is uniformly reduced in the bacterial overgrowth syndromes; the defect is not corrected by administration of intrinsic factor, but is transiently corrected by prior administration of certain antibiotics, especially tetracyclines.<sup>116,132</sup> Most probably, the absorptive defect represents successful competition by the bacteria for dietary vitamin B<sub>12</sub>. The bacteria appear to be able to take up and bind the vitamin so firmly that it is essentially unavailable to the host.<sup>106,109</sup> The amount of the vitamin bound greatly exceeds the needs of the bacteria.<sup>114</sup> Surgical correction of the anatomic lesion of the bowel leads to normalization of the bowel flora and restoration of normal vitamin B<sub>12</sub> absorption.<sup>111</sup>

### Fish Tapeworm Disease

In Finland, megaloblastic anemia due to vitamin B<sub>12</sub> deficiency has been observed in 1.9 to 3.0% of carriers of the fish tapeworm, *Diphyllobothrium latum*.<sup>134</sup> *D. latum*, a common parasite of freshwater fish, especially pike, is widely distributed in the lakes of many parts of Europe as well as those of north central North America. Human infection results from ingestion of inadequately cooked fish. Despite the wide distribution of

the parasite, it rarely, if ever, causes megaloblastic anemia outside of Finland. The reason for the precise geographic distribution is not clear; that a constitutional predisposition is required before anemia develops has been suggested.<sup>103</sup> More likely, the development of deficiency depends on the mass of worms harbored by the patient.<sup>115</sup> This in turn may be related to the dietary habits of the Finns or to special characteristics of the variety of *D. latum* in Finland.

The deficiency of vitamin B<sub>12</sub> results from impaired absorption. Little, if any, improvement in absorption was observed when the vitamin was given with intrinsic factor.<sup>134</sup> As in the bacterial overgrowth syndromes, the malabsorption probably results from competition between the worm and the host for dietary vitamin B<sub>12</sub>. The tapeworm is able to take up and bind the vitamin firmly.<sup>134</sup> It lodges in the ileum in carriers without anemia, whereas in those with anemia the site of attachment tends to be in the jejunum.<sup>104</sup> Apparently, this latter location enables the worm to bind the vitamin before it reaches the sites of absorption in the ileum.

The anemia responds to expulsion of the worms,<sup>134</sup> but the response often is suboptimal if no vitamin B<sub>12</sub> is given.<sup>104</sup> Vitamin B<sub>12</sub> is effective even when the worms are not expelled.

### Familial Selective Vitamin B<sub>12</sub> Malabsorption (Imerslund's Syndrome)<sup>122</sup>

This inherited illness is characterized by the onset of megaloblastic anemia in childhood, usually during the first two years of life, and by persistent proteinuria.<sup>131</sup> The disease is rare, only 38 cases having been reported.<sup>170,131,139</sup> It appears to be inherited as an autosomal recessive trait.

Patients with this disorder are unable to absorb vitamin B<sub>12</sub> whether or not it is bound to intrinsic factor. Except in one patient,<sup>139</sup> other abnormalities of intestinal absorption have not been observed. Furthermore, there is no defect in gastric secretion, nor are gas-

tric autoantibodies (page 606) found. The anemia responds completely to vitamin B<sub>12</sub>, but the proteinuria persists. In heterozygotes, defects in vitamin B<sub>12</sub> absorption lesser in severity than in homozygotes have been reported, but anemia does not develop.<sup>131</sup>

The nature of the inherited lesion remains unknown. It has been suggested that ileal receptors for vitamin B<sub>12</sub> are defective,<sup>131</sup> but in at least one well-studied patient, ileal homogenates bound the vitamin normally, indicating that the receptor sites were intact.<sup>130</sup> This observation, together with the absence of morphologic lesions as seen by light or electron microscopy of ileal biopsy specimens, suggests that the inherited lesion impairs a stage of vitamin B<sub>12</sub> absorption that follows ileal attachment of the intrinsic factor-B<sub>12</sub> complex.

#### ***Drug-Induced Vitamin B<sub>12</sub> Malabsorption***

Megaloblastic anemia is a rare effect of para-aminosalicylic acid (PAS) therapy, having been observed in only two subjects receiving the drug for treatment of tuberculosis.<sup>118</sup> A moderate degree of vitamin B<sub>12</sub> malabsorption is found, however, in nearly all subjects who consume PAS for more than six weeks. The defect appears to be "selective," in that fat and xylose absorption are unaffected. Intrinsic factor secretion is not impaired. The absorptive defect disappears about two weeks after use of the drug is discontinued. Reversible malabsorption of vitamin B<sub>12</sub> has also been observed in patients taking colchicine,<sup>140</sup> neomycin,<sup>123</sup> ethanol,<sup>128</sup> or potassium chloride.<sup>136</sup>

#### ***Chronic Pancreatic Disease***

Defective absorption of vitamin B<sub>12</sub>, correctable with oral administration of pancreatic enzyme, was detected in nine of 22 patients with pancreatic exocrine insufficiency.<sup>138</sup> Megaloblastic anemia has been observed only rarely in association with this disorder, however, possibly because the de-

fect usually is not severe enough nor of sufficient duration for deficiency to develop. A similar abnormality can be induced in rats by partial pancreatectomy.<sup>138</sup>

#### ***Zollinger-Ellison Syndrome***

Impaired vitamin B<sub>12</sub> absorption without megaloblastic anemia was observed in patients with Zollinger-Ellison syndrome, probably because of the low pH of intestinal contents reaching the ileum.<sup>137</sup>

#### ***Diseases Affecting the Ileum***

Since vitamin B<sub>12</sub> is absorbed chiefly in the ileum, ileal resection or bypass or diseases that may be localized to the ileum lead to malabsorption of the vitamin. Vitamin B<sub>12</sub> malabsorption has been observed in patients who have had as little as 1 foot of ileum resected, and probably is always impaired if more than 6 feet are removed.<sup>105,113</sup> Absorption of the vitamin was uniformly impaired in six patients after they had had ileal bypass operations.<sup>107</sup> In contrast, resection of the jejunum does not usually affect vitamin B<sub>12</sub> absorption, but may impair folate absorption.

The terminal ileum is affected in about 80% of patients with regional enteritis (Crohn's disease), and about 18% of such patients have been found to have megaloblastic anemia.<sup>23</sup> Both folate deficiency and vitamin B<sub>12</sub> deficiency may occur in association with regional enteritis, but there are no good data indicating relative frequency of the two deficiencies.

#### ***Dietary Folate Deficiency***

That a short period of dietary deprivation can lead to folate deficiency in an otherwise healthy individual has been demonstrated convincingly.<sup>40</sup> Normal body folate stores remain adequate for only two to four months following the institution of a deficient diet, and in this respect folate differs markedly from vitamin B<sub>12</sub>, the stores of which can last for several years.

Nutritional folate deficiency is especially common in tropical areas such as India,<sup>246,263</sup> Burma,<sup>224</sup> Singapore,<sup>253</sup> Malaysia,<sup>258</sup> and Africa.<sup>201, 214, 260</sup> In these areas the inadequate diet is chiefly a consequence of extreme poverty, but ignorance, customs, and religious tenets may also affect intake adversely. The diets associated with the development of folate deficiency are characterized by a pre-dominance of starches and grains with relatively little animal protein or fresh, green vegetables. In a number of these areas, tropical sprue (see below) is endemic, and the relative importance of this illness and nutritional factors has not been easy to assess.<sup>23</sup> When vitamin B<sub>12</sub> deficiency is associated with "tropical macrocytic anemia,"<sup>204</sup> it is usually considered to be caused by tropical sprue.

Nutritional folate deficiency has also been found in relatively affluent populations living in temperate areas.<sup>211, 213, 217, 218, 243, 261</sup> Major factors contributing to the consumption of poor diets in such people were mental disturbances, chronic illness, alcoholism, old age, food fadism, and poverty. Dietary folate deficiency may occur more often in Great Britain than in the United States because of habitual use, in Great Britain, of vegetable cooking methods utilizing long exposure to heat and water.<sup>220</sup>

### *Cirrhosis*

Megaloblastic anemia has been observed in about 20% of patients with alcoholic cirrhosis.<sup>2, 7, 226, 227, 232</sup> In some of the subjects the marrow has been said to have "transitional" megaloblastic changes, perhaps because the morphologic characteristics have been modified by coexisting iron deficiency.<sup>227</sup> The incidence of megaloblastic anemia in association with cirrhosis may be as great as 50% or more if the diagnosis is made on the basis of such early signs as macroovalocytosis of the red cells and hypersegmentation of the granulocytes.<sup>219</sup> In general, the patients with megaloblastic anemia tend to have more se-

vere degrees of anemia and more pronounced macrocytosis (MCV greater than 120 fl) than do patients with non-megaloblastic macrocytic anemia associated with liver disease (Chapter 19, page 706).<sup>2, 226</sup>

Megaloblastic anemia in patients with cirrhosis almost always is the consequence of folate deficiency. Serum folate levels are reduced,<sup>219, 226, 230, 243</sup> formiminoglutamate (FIGlu) excretion (page 586) is increased,<sup>207</sup> and vitamin B<sub>12</sub> levels are normal or increased.<sup>227, 243</sup> The folate deficiency results chiefly from inadequate dietary intake.<sup>219, 230</sup> However, there also is evidence of disordered folate metabolism, as manifested by decreased ability of the liver to store folate<sup>208</sup> and excessive urinary loss of the vitamin.<sup>247</sup> Because of this, there is an increased need for dietary folate in patients with liver disease.

### *Pregnancy*

The megaloblastic anemia of pregnancy probably is the most common of all folate deficiency states.<sup>23</sup> It has been discussed in Chapter 13 in relation to other forms of anemia occurring during pregnancy.

### *Infancy*

In 1946, Zuelzer and associates called attention to the occurrence in infants (age two to 16 months) of folate-deficiency megaloblastic anemia resulting from increased needs, dietary inadequacy, and superimposed infection.<sup>265</sup> Within the next few years, their observation was followed by reports of over 100 cases. In about a quarter of the reported patients, evidence of coexisting scurvy was found. There was a rapid decrease in the number of reported cases after vitamin C was added to infant feeding formulas.<sup>234, 237, 239, 263</sup> These observations led to speculation that vitamin C was required in some way for normal folate metabolism.<sup>242</sup> No evidence supporting this speculation was forthcoming, and in retrospect it is likely that the affected infants had a simultaneous de-

iciency of vitamin C and folate. Vitamin C added to the feeding formulas probably acts as a preservative for their intrinsic folate content, especially when the formulas are heated during preparation.

Megaloblastic anemia is now uncommon among infants in well-developed, affluent countries. It continues to be observed in areas where malnutrition is widespread,<sup>235,239,262</sup> for example, those in which kwashiorkor is endemic.<sup>23,235</sup>

The normal requirement for folate in infancy has been estimated to be about 50  $\mu\text{g}/\text{day}$ , or about four to ten times the adult requirement on a weight basis.<sup>257</sup> Normal human milk and raw or pasteurized cow's milk contain about 50  $\mu\text{g}$  of folate per liter.<sup>216,241</sup> Thus, with normal rates of milk intake, the infant requirements for folate can be satisfied with milk alone. However, boiling leads to a 40 to 80% reduction in the folate content of milk, and folate is partially destroyed in preparing powdered milk. In general, serum folate levels are higher in breast-fed than in bottle-fed infants.<sup>240</sup> Nevertheless, megaloblastic anemia has been reported in breast-fed infants,<sup>203</sup> possibly because of decreased amounts of folate in the milk of mothers with marginal folate stores.<sup>256</sup>

Goat's milk contains very low amounts of folate (average, 6  $\mu\text{g}/\text{l}$ ).<sup>216,241</sup> "Goat's milk anemia" is a form of megaloblastic anemia of infancy occurring in babies fed goat's milk exclusively. First described in Germany and Italy, it has also been observed in the United States,<sup>257,265</sup> Australia,<sup>264</sup> and New Zealand.<sup>203</sup>

Nutritional folate deficiency in infants must be distinguished from certain other disorders causing megaloblastic anemia in this age group. These disorders include congenital pernicious anemia (Chapter 15), familial selective vitamin  $\text{B}_{12}$  malabsorption (page 576), celiac disease (page 580), and inborn errors of DNA synthesis (page 581). Also, vitamin  $\text{B}_{12}$  deficiency has been observed in the breast-fed infant of a mother with subclinical pernicious anemia.<sup>233</sup>

### *Rapid Cellular Proliferation*

Folate deficiency with megaloblastosis has been observed as a complication of a variety of hematologic illnesses. These include sickle cell anemia,<sup>202,236</sup> thalassemia,<sup>225,250</sup> hereditary spherocytosis,<sup>210,231</sup> acquired autoimmune hemolytic anemia,<sup>212</sup> drug-induced hemolytic anemia with glucose-6-phosphate dehydrogenase deficiency,<sup>245</sup> paroxysmal nocturnal hemoglobinuria,<sup>244</sup> myelofibrosis,<sup>222</sup> sideroblastic anemia,<sup>223,238</sup> leukemia,<sup>251</sup> and multiple myeloma.<sup>221</sup> The complication is associated with a fall in the VPRC from previously stable levels or with an increase in transfusion requirements.

These disorders have in common a rapid proliferation of red cells or other marrow elements. It is reasonable to assume that the need for DNA synthesis, and therefore the need for folate, is increased under such circumstances. Often, however, there have been other coexisting reasons for folate deficiency in the reported patients, including pregnancy and deficient diet.

### *Congenital Folate Malabsorption*

Congenital folate malabsorption is an extremely rare disorder, having been reported in only three patients in two different families.<sup>234</sup> In addition to the absorptive disorder, defective transfer of folate to the central nervous system associated with mental retardation and ataxia was observed.

### *Drug-Induced Folate Malabsorption*

Severe megaloblastic anemia has been observed in patients taking anticonvulsant drugs.<sup>228,249,254</sup> The drugs implicated in the majority of these patients were diphenylhydantoin (Dilantin), primidone (Mysoline), and phenobarbital, alone or in combination. Although well-marked megaloblastic anemia was unusual, evidence of folate deficiency and mild hematologic changes were relatively common. For example, serum folate levels were reduced in 31 to 76% of unselected

patients receiving anticonvulsants.<sup>23,209,229</sup>  
<sup>259</sup> In one series, serum folate values were subnormal in 76% and megaloblastosis was found in 38% of 45 nonanemic patients.<sup>219</sup>

Anticonvulsant drugs appear to exert their effects by impairing folate absorption.<sup>215</sup> This abnormality may result from inhibition of intestinal conjugase with consequent failure to absorb folic polyglutamates.<sup>252</sup> However, in one study, no *in vitro* evidence for conjugase inhibition could be found, and it was suggested that it is absorption of free folate that is defective.<sup>206</sup> This controversy will probably be resolved in the near future when labeled folic polyglutamates and monoglutamates become available for absorption tests.

A similar defect in folate absorption with associated megaloblastic anemia has been reported in women taking oral contraceptive medications.<sup>255,259</sup> When oral tolerance tests were performed in a nondeficient group of women taking contraceptives, absorption of folate monoglutamate appeared to be normal, but folate polyglutamate absorption was impaired.<sup>251</sup>

### *Tropical Sprue and Gluten-Sensitive Enteropathy*

Tropical sprue and gluten-sensitive enteropathy are similar in that both bring about a generalized state of intestinal malabsorption characterized by steatorrhea, weight loss, weakness, and deficiency of a wide variety of nutrients. The morbid anatomy in both is characterized by varying degrees of villous atrophy with loss of intestinal surface. In gluten-sensitive enteropathy, the lesions are most severe in the proximal intestine, and the ileum is involved in only a minority of the patients.<sup>281</sup> In tropical sprue, the lesions tend to be less severe but more extensive, the whole of the small intestine being affected.<sup>279</sup> The diseases differ not only in their geographic distribution, but also in pathogenesis and response to specific modes of therapy.

*Tropical sprue*<sup>279</sup> is endemic in most of the West Indies, South India, Southeast Asia, Malaysia, and Indonesia; it is rare, however,

in certain other tropical areas, such as Jamaica, Africa, and South America. There have been reports of patients who developed the illness months to years after leaving an endemic area. Although the cause of the illness is unknown, an infectious origin seems probable on the basis of observed responses to antibiotic therapy<sup>277,279</sup> and on epidemiologic grounds.<sup>271</sup> A specific infectious agent has not been identified with certainty, but preliminary evidence suggests that it might be the zygote form of the alga, *Prototheca portoricensis*.<sup>272</sup> If this cause can be established, tropical sprue would be the first known algal disease in man.

Three clinical stages of tropical sprue have been recognized.<sup>276,285</sup> The initial phase is characterized by the abrupt onset of diarrhea, anorexia, abdominal distension, and extreme asthenia. After an interval of weeks to months, the second, or "deficiency" phase occurs as the result of prolonged malabsorption and depletion of nutrients. Weight loss, glossitis, stomatitis, hyperkeratosis, and continuing weakness are prominent in this stage. In the third phase, megaloblastic anemia develops. Since the intestinal lesion tends to be generalized, absorption of both folate and vitamin B<sub>12</sub> is impaired. In disease of relatively short duration, folate deficiency predominates, whereas in the more chronic forms of the illness, vitamin B<sub>12</sub> deficiency occurs as well.<sup>23</sup> The described sequence of events is not invariable, and patients with megaloblastic anemia may be observed who have not experienced the other clinical manifestations of tropical sprue.

Administration of folate to patients with tropical sprue not only induces hematologic remission, but also may bring about improvement in intestinal symptoms and pathologic lesions.<sup>286</sup> In about 50% of patients, however, intestinal dysfunction may persist after folate therapy, and may later respond to antibiotics.<sup>277</sup>

*Gluten-induced enteropathy* is a term that includes both celiac disease of children and nontropical sprue (idiopathic steatorrhea) in adults. The illness represents a possibly inherited,<sup>280,281</sup> abnormal reaction to gluten, a

water-insoluble, glutamine-rich protein fraction of wheat and other grains. The mechanism of gluten sensitivity is not understood; it has been suggested that the patients lack an intestinal peptidase that normally acts to detoxify a toxic peptide in gluten.<sup>270</sup>

In addition to weight loss, abdominal distension, and steatorrhea, patients with gluten-induced enteropathy may develop negative calcium balance with hypocalcemia, tetany, and demineralization of bones, with consequent bone pain and pathologic fractures. They may also develop deficiency of vitamin K-dependent coagulation factors (Chapter 38).

In celiac disease in children, the most common cause of anemia is iron deficiency,<sup>274</sup> but folate deficiency occurs in 10 to 40%. Vitamin B<sub>12</sub> deficiency is unusual. In the adult form of the disease, folate malabsorption and deficiency are found in about 90% of patients, whereas vitamin B<sub>12</sub> malabsorption and deficiency are found in only about 40%,<sup>23</sup> presumably because the ileum often is spared.<sup>253</sup> Iron stores often are reduced, but the anemia rarely appears hypochromic until the megaloblastic defect has been corrected. To obtain an optimal hematologic response to folate or vitamin B<sub>12</sub>, concurrent or subsequent iron therapy may be required. With a gluten-free diet the blood returns to normal over a period of several months.<sup>275</sup>

In occasional patients, folate malabsorption seems out of proportion to the other intestinal abnormalities. Such patients manifest megaloblastic anemia without other clinical evidence of malabsorption ("temperate sprue").<sup>273</sup> Whether this represents a unique illness or a variant of nontropical sprue is uncertain.

Certain abnormalities are demonstrable by laboratory tests in both tropical sprue and gluten-induced enteropathy. Total stool fat is increased<sup>282</sup> and D-xylose absorption is defective.<sup>284</sup> Serum carotene and vitamin A levels usually are reduced.<sup>288</sup> A "malabsorption pattern" is observed on roentgenographic study of the intestine<sup>287</sup>; the jejunum is dilated, the barium column becomes bro-

ken up into segments, the valvulae conniventes may be obliterated or widely separated, and the bowel segments may resemble "a tube into which wax has been poured and allowed to harden" (moulage sign)<sup>278</sup> (Fig. 14-7). Subtotal villous atrophy is found on jejunal biopsy.<sup>279,283</sup> The diagnosis of gluten sensitivity usually requires that a response to a gluten-free diet be demonstrated. Alternatively, when the diagnosis is difficult to establish, the patient may be challenged with an oral dose of 30 to 50 g of gluten which, in sensitive subjects, is followed by a prompt increase in diarrhea and fecal fat loss.

When the manifestations of tropical sprue and gluten-induced enteropathy are tabulated and compared with those in pernicious anemia, it becomes evident that there are certain clinical similarities in the illnesses, but that certain manifestations tend to predominate in each (Table 14-4). Cases of pernicious anemia are encountered in which glossitis and diarrhea are so prominent that differentiation from sprue is difficult; conversely, when the intestinal manifestations of sprue are not prominent, the disease may appear similar to pernicious anemia.

### *Inherited Disorders Affecting DNA Synthesis*

**OROTIC ACIDURIA.** This is an inherited disorder of pyrimidine metabolism characterized by megaloblastic anemia and excessive urinary excretion of orotic acid.<sup>301</sup> In most of the patients reported, growth and development were retarded. The illness probably is transmitted as an autosomal recessive trait, and is very rare, having been reported in only seven patients.<sup>296,299,301,303</sup> In six of the seven, the disease resulted from greatly reduced activity of two enzymes, orotidylic pyrophosphorylase and orotidylic decarboxylase, both of which are required for the conversion of orotic acid to uridine-5-phosphate. In the seventh patient, the activity of only one of the two enzymes (orotidylic decarboxylase) was reduced.<sup>296</sup> In heterozygotes, the activity of the two enzymes may be somewhat reduced, and slightly increased

Fig 14.7 Roentgenogram showing the gastrointestinal tract two hours following a barium meal in a patient with sprue. The stomach is almost completely empty. The barium is distributed throughout the small intestine and has reached as far as the splenic flexure of the large intestine. The small bowel shows the characteristic 'moulage' sign. The pattern of an irritative lesion in the jejunum is shown by the many small irregular collections of barium on the left side of the abdomen.

values for urinary orotic acid may be found, but no disease results.<sup>295</sup> Orotic aciduria does not respond to folate or vitamin B<sub>12</sub>, but administration of uridine (1 to 1.5 g/day) leads to hematologic remission and restoration of normal growth and development.

**LESCH-NYHAN SYNDROME.** This is an X-linked disorder of purine metabolism, characterized by hyperuricemia, self-mutilation, and mental and neurologic defects. It results from a lack of the enzyme hypoxanthine-guanine phosphoribosyl-transferase. In one case, the syndrome included megaloblastic anemia which responded to the administration of adenine.<sup>306</sup>

**THIAMIN-RESPONSIVE MEGALOBlastic ANEMIA.** An 11 year old girl with severe megaloblastic anemia, diabetes mellitus, aminoaciduria, and sensorineural deafness was reported.<sup>300</sup> She failed to respond to folate, vitamin B<sub>12</sub>, uridine, or many other nutrients; however, on two occasions, a reticulocytosis and a rise to normal in the hemoglobin level were observed when thiamin was administered in a dose of 20 mg per day. The nature of the metabolic defect was not elucidated.

**N<sup>5</sup>-METHYL TETRAHYDROFOLATE TRANSFERASE DEFICIENCY.** A single case of congenital megaloblastic anemia and mental retardation

**Table 14-4. Comparison of Certain Manifestations of Pernicious Anemia, Tropical Sprue, and Gluten-Induced Enteropathy**

	Pernicious Anemia	Tropical Sprue	Gluten Enteropathy
Mental symptoms	+	-	-
Neurologic disease	++	+	-
Absence of intrinsic factor	+++	+	-

Hypochromic anemia	-	+	++
Bone deformities	-	-	+++

\*Especially in children

tion associated with very high serum folate levels has been reported.<sup>291</sup> Presumably the serum folate could not be utilized, since a reticulocyte response followed treatment with folic acid. In liver specimens, there was a severe decrease in activity of the enzyme catalyzing the conversion of N<sup>5</sup>-methyl tetrahydrofolate to tetrahydrofolate.

**FORMIMINOTRANSFERASE DEFICIENCY.** This inborn error of folate metabolism has been detected in four subjects. Three were hematologically normal, but one had "megaloblastic and sideroblastic" anemia.<sup>291</sup>

**DIHYDROFOLATE REDUCTASE DEFICIENCY.** In a patient with congenital megaloblastic anemia, dihydrofolate reductase activity in liver tissue was found to be markedly reduced.<sup>304</sup> The patient did not respond to folic acid but did respond to folinic acid (N<sup>5</sup>-formyltetrahydrofolic acid), a reduced form of the vitamin. It was concluded that the findings in this patient were best explained by a congenital lack of dihydrofolate reductase.

**TRANSCOBALAMIN II DEFICIENCY.** Two sisters developed growth failure and megaloblastic anemia at ages three and five weeks.<sup>297</sup> The vitamin B<sub>12</sub> transport protein, transcobalamin II, was lacking in the sera of both,

and this defect probably was inherited as an autosomal recessive trait. Both infants responded to high-dose (2000 µg/week) vitamin B<sub>12</sub> therapy, and in one of them relapse occurred six weeks after therapy was withdrawn.

**CONGENITAL MEGALOBlastic ANEMIA RESPONSIVE TO COMBINED, LARGE-DOSE FOLATE AND VITAMIN B<sub>12</sub> THERAPY.** The occurrence of congenital megaloblastic anemia in two sisters was reported.<sup>298</sup> Serum vitamin B<sub>12</sub> and serum erythrocyte folate levels were normal. Optimal hematologic response required the simultaneous administration of both folate and vitamin B<sub>12</sub> in large doses. The nature of the defect was not determined.

### *Drug-Induced Disorders of DNA Synthesis*

Megaloblastic anemia is a predictable toxic effect of a variety of drugs used in the chemotherapy of leukemia and solid tumors (Chapter 55). The complication has been reported with 6-mercaptopurine, 5-fluorouracil,<sup>294</sup> cyclophosphamide,<sup>293</sup> cytosine arabinoside,<sup>302</sup> and the folate antagonists.<sup>305</sup> In these situations, the toxic effect is an extension of the therapeutic effect. The drugs are used because they interfere with DNA synthesis and therefore inhibit growth of rapidly dividing tissues. When toxicity occurs, pancytopenia and hypersegmented neutrophils are found, as well as oval macrocytes in the blood and megaloblasts in the bone marrow.

The folate antagonists, of which amethopterin (methotrexate) is the most commonly used example, act chiefly by competitive inhibition of dihydrofolate reductase.<sup>305</sup> When this enzyme is inhibited, dietary folate cannot be converted to the active, tetrahydro form, and endogenous folate accumulates as the inactive dihydrofolate.

Inhibition of dihydrofolate reductase has been reported as a side effect of drugs used for other purposes. These drugs include pyrimethamine, triamterene, pentamidine, and trimethoprim.<sup>305</sup> They are much less potent antagonists than methotrexate, and are likely to produce megaloblastic anemia only in individuals with borderline folate stores.

### Erythroleukemia (Di Guglielmo Syndrome)

Megaloblasts, or cells resembling them, have been described in the blood and marrow of patients with neoplastic proliferation of red cell precursors<sup>292</sup> (see Chapter 48). In these subjects, the megaloblasts do not disappear after treatment with vitamin B<sub>12</sub> or folate, and serum levels of these vitamins are either normal or increased. This syndrome must be distinguished from acute leukemia complicated by folate deficiency (page 574) and from sideroblastic anemia associated with folate deficiency (page 579).

### Laboratory Tests Useful in the Differential Diagnosis of Megaloblastic Anemia

#### Vitamin B<sub>12</sub> and Folate Levels in Serum and Erythrocytes

Determination of serum vitamin B<sub>12</sub> and folate levels provides a valuable means for distinguishing the two deficiency states from one another (Table 14-5). Vitamin B<sub>12</sub> levels may be determined microbiologically<sup>311,333</sup> or by isotope dilution.<sup>331</sup> Serum and erythrocyte folate concentrations usually have been determined microbiologically,<sup>328</sup> but a promising isotope dilution method has been described.<sup>310</sup> In the microbiologic assays, falsely low results may be observed in patients receiving antibiotics.

Most of the vitamin B<sub>12</sub> in serum is bound to transcobalamin I (Chapter 4) and is in equilibrium with tissue stores. Thus, the serum vitamin B<sub>12</sub> level usually is a reliable index of the total body vitamin content. There is a relatively wide difference between normal values and those found in vitamin B<sub>12</sub> deficiency (Table 14-5); however, values falling between about 120 and 180 ng/l are considered to be in a "gray zone," neither clearly normal nor clearly abnormal.<sup>23</sup> In one study, the marrow became megaloblastic when serum B<sub>12</sub> levels fell to between 70 and 154 ng/l.<sup>403</sup> The diagnostic usefulness of serum B<sub>12</sub> levels is somewhat limited by the observation that they may be subnormal in patients with folate deficiency.<sup>335,345</sup> In about half of such patients, the values were found to be less than 180 ng/l and, in about 10%, less than 100 ng/l.<sup>335</sup> In patients deficient in folate, but not in those deficient in vitamin B<sub>12</sub>, serum vitamin B<sub>12</sub> levels returned to normal when folate was administered.<sup>23,333</sup>

In contrast to serum vitamin B<sub>12</sub>, serum folate is relatively labile, being sensitive to short-term changes in folate balance.<sup>23</sup> Thus, the serum folate may increase within a few hours after consumption of folate-containing food. Furthermore, a low intake of folate may result in reduced serum levels before true deficiency develops.<sup>40</sup> The erythrocyte folate level is a better index of tissue folate stores, and its significance with respect to folate deficiency is more nearly equivalent to that

Table 14-5. Vitamin B<sub>12</sub> and Folate Levels in Normal Subjects and in Vitamin B<sub>12</sub> and Folate Deficiency

	Normal Subjects*	Vitamin B <sub>12</sub> Deficiency*	Folate Deficiency*
Serum vitamin B <sub>12</sub> <sup>23</sup> (ng/l)	450† (160-1000)†	38 (<10-110)	190 (50-500)
Serum folate <sup>344</sup> (ng/l)	10† (6-21)†	17 (4-37)	<3
RBC folate <sup>330</sup> (ng/l)	316† (166-640)†	146 (26-395)	<100

\*Values are means with range in parentheses

†Normal values may be expected to vary somewhat with the method used and from one laboratory to another

of serum vitamin  $B_{12}$  levels in vitamin  $B_{12}$  deficiency. In patients with folate deficiency, values for both serum and erythrocyte folate are found to be subnormal. In patients with vitamin  $B_{12}$  deficiency, serum folate levels tend to be increased, and, in about 25%, exceed the upper limit of normal. In contrast, erythrocyte folate levels fall (Table 14-5). This discrepancy between the two measurements presumably is the consequence of an accumulation of folate as 5-methyl tetrahydrofolate, the form which predominates in serum (see Chapter 4). Vitamin  $B_{12}$  appears to be required for the normal transfer of 5-methyl tetrahydrofolate from plasma to cells.<sup>343</sup> On the other hand, for reasons that are not clear, serum folate levels may decrease in a small proportion (2 to 10%) of vitamin  $B_{12}$  deficient subjects.<sup>23</sup>

Because of the occasional overlap in values between subjects with vitamin  $B_{12}$  deficiency and those with folate deficiency, it is usually wise to determine serum levels of both vitamins at the same time, as well as erythrocyte folate, if available. For example, in a patient with folate deficiency there may be modest reductions in serum vitamin  $B_{12}$  levels, but serum and erythrocyte folate levels are likely to be more profoundly depressed (Table 14-5). Conversely, the typical patient with vitamin  $B_{12}$  deficiency will have reduced

serum vitamin  $B_{12}$  and erythrocyte folate levels, with increased values for serum folate.

### *The Deoxyuridine (dU) Suppression Test<sup>9,334,342</sup>*

This test is a sensitive measure of a lack of 5,10 methylene tetrahydrofolate at the cellular level, an abnormality which occurs with deficiency of either folate or vitamin  $B_{12}$ . Correction of the abnormality by the addition of one of these vitamins helps to determine the nature of the deficiency. If deoxyuridine (dU) is added to normal marrow cultures, it is incorporated into DNA (Fig. 14-8). This reduces the rate of incorporation of subsequently added  $^3H$ -thymidine to less than 10% of the rate in marrow cultures without dU. With marrows collected from subjects with megaloblastic anemia, the conversion of dU to deoxythymidine monophosphate (dTMP) is inhibited (Fig. 14-8) and, therefore, a lesser degree of suppression of  $^3H$ -thymidine incorporation by dU is observed. The abnormality can be corrected by adding folic acid, whether there is either folate deficiency or vitamin  $B_{12}$  deficiency. Adding vitamin  $B_{12}$  corrects the defect only in vitamin  $B_{12}$  deficiency.<sup>9</sup> If minimally effective concentrations of the vitamins are used, selective correction only by the defi-

Fig. 14-8. Pathways of folate metabolism involved in the incorporation of deoxyuridine (dU) into DNA. THF, tetrahydrofolate;  $FH_2$ , dihydrofolate; dUMP, deoxyuridine monophosphate; dTMP, deoxythymidine monophosphate

cient vitamin is observed, and the procedure constitutes a "test-tube therapeutic trial."<sup>312</sup> Preliminary studies indicate that <sup>125</sup>I-uridine deoxyriboside can be substituted for <sup>3</sup>H-thymidine, making isotopic analysis considerably simpler.<sup>312</sup>

### Urinary Excretion of Metabolites

**METHYLMALONATE.** A vitamin B<sub>12</sub> coenzyme is required for the conversion of methylmalonyl coenzyme A to succinyl coenzyme A, a step in the catabolism of propionate (Chapter 4). In subjects with vitamin B<sub>12</sub> deficiency, urinary excretion of methylmalonic acid usually is increased, and this phenomenon appears to provide a specific and moderately sensitive test for the deficiency.<sup>319</sup> Unfortunately, none of the available methods is both simple and accurate enough for routine clinical use. The most accurate techniques require both ion-exchange chromatography and gas chromatography.<sup>319,323</sup> Colorimetric methods<sup>323,326,346</sup> are simpler, but less reproducible. Thin layer chromatographic methods may represent a reasonable compromise.<sup>320</sup>

Normal subjects excrete no more than 9 mg of methylmalonate in 24 hours and excretion is not increased by the prior oral administration of 10 g valine, a methylmalonate precursor.<sup>325</sup> In vitamin B<sub>12</sub> deficiency, baseline methylmalonate excretion is as much as 300 mg/day.<sup>319,325,326</sup> Occasional deficient patients may excrete normal amounts, possibly because of coincidental caloric deprivation.<sup>345</sup> In most, if not all such patients, prior administration of 10 g valine brings about a pronounced increase in urinary methylmalonate and the value then becomes abnormal.<sup>323</sup>

Normal results are obtained in patients with folate deficiency both before and after valine administration.

**FORMIMINOGLUTAMATE (FIGLU).** This compound is an intermediate in the conversion of histidine to glutamate (Chapter 4). The final step in the pathway consists of the formation of glutamate from FIGlu by the transfer of the formimino group to tetra-

hydrofolate. In folate deficiency, this step is impaired, and FIGlu is excreted in the urine. In the FIGlu excretion test, a loading dose (usually 15 g) of histidine is given and urine is collected for eight hours. Urinary FIGlu is measured most accurately by spectrophotometry.<sup>315</sup> Normal subjects excrete 1 to 17 mg of FIGlu in the eight-hour period. Excretion is almost always increased in folate-deficient subjects. In one series of 245 such patients, the value ranged from 185 to 2047 mg/8 hr.<sup>332</sup>

Increased FIGlu excretion is also found in more than 50% of patients with vitamin B<sub>12</sub> deficiency, a phenomenon that limits the diagnostic utility of the test. Usually, but not always, the amount excreted is less than that found in folate deficiency. In 16 of 18 patients with vitamin B<sub>12</sub> deficiency, FIGlu excretion ranged from 23 to 260 mg/8 hr.<sup>315</sup>

**AMINOIMIDAZOLE CARBOXAMIDE (AICAR).** This is an intermediate in purine synthesis that is metabolized in a folate-dependent step. Like FIGlu, it is excreted in excess in both folate and vitamin B<sub>12</sub> deficiency.<sup>329</sup>

### Therapeutic Trial

The uses of therapeutic trials were discussed in Chapter 13 (page 552). Although diagnosis by trial is somewhat time-consuming, the procedure is readily available where other laboratory facilities may be limited. It is essential, however, that the trial be conducted under the conditions outlined as otherwise it can be very misleading.

### Tests of Vitamin B<sub>12</sub> Absorption

Absorption of vitamin B<sub>12</sub> labeled with radioactive cobalt can be measured by several techniques.<sup>324</sup> Of the four available isotopes, <sup>57</sup>Co and <sup>58</sup>Co are the most satisfactory from the standpoint of radiation safety.<sup>339</sup> <sup>56</sup>Co and <sup>60</sup>Co have also been used, but the radiation exposure is considerably greater. <sup>57</sup>Co, a low-energy gamma emitter, is especially useful when determinations of plasma radioactivity are to be made, whereas <sup>58</sup>Co, which

emits both gamma rays and beta particles, is suitable for most other purposes, including in vivo counting over body surfaces.

In measuring absorption, a physiologic dose (usually 0.5, 1.0, or 2.0  $\mu\text{g}$ ) of the labeled vitamin is given by mouth. Absorption is estimated by assays of fecal<sup>334</sup> or urinary<sup>317,321,341</sup> excretion, serum levels,<sup>312,316,317,318</sup> total body content,<sup>314,317,327,338</sup> or hepatic uptake.<sup>322,324</sup> Without doubt, the most accurate methods are those which employ total body counting; however, the complexity and cost of the required equipment have limited the availability of the procedure. Methods depending on serum levels or hepatic uptake have the advantage of being independent of accurate collection of excreta; however, both may be affected by an abnormal distribution of the absorbed vitamin to various body sites. Fecal excretion tests require a prolonged and scrupulously complete collection of feces until all radioactivity has been excreted, which may take as long as seven to eight days. Furthermore, unless large volume counting instruments are available, the disagreeable specimens must be adequately mixed and processed so that a representative sample can be assayed.

By far, the most popular method for testing vitamin  $B_{12}$  absorption has been *Schilling's urinary excretion test*, which is comparatively simple to carry out.<sup>324,341</sup> In this test, a so-called "flushing dose" of 1000  $\mu\text{g}$  of nonradioactive vitamin  $B_{12}$  is injected intramuscularly at the same time as, or one to two hours after, 0.5 to 2.0  $\mu\text{g}$  of the labeled vitamin is given orally, and radioactivity is assayed in a urine specimen collected for 24 to 72 hours thereafter. The purpose of the injection is to partially saturate body binding sites, thereby bringing about the urinary excretion of the vitamin which would otherwise be retained. A relatively constant proportion (about 34%) of the absorbed radioactive vitamin is excreted under these conditions.<sup>23,313,317</sup> Some investigators have administered a second 1000- $\mu\text{g}$  dose of nonradioactive vitamin  $B_{12}$  24 hours after the first.<sup>321</sup> This procedure brings about the ex-

cretion of an additional small fraction of the absorbed vitamin; also, the accuracy of a subsequent test employing added intrinsic factor is improved, because the chance of contamination with label from the prior test dose is minimized.

Representative values obtained with the Schilling test are given in Table 14-6. In pernicious anemia and other disorders in which intrinsic factor is lacking, vitamin  $B_{12}$  absorption is markedly reduced, and the value is corrected toward normal by administering intrinsic factor with the orally administered vitamin. In non-tropical sprue, (gluten-induced enteropathy), the value is also reduced, although not always to the same degree as in pernicious anemia. Sprue can be distinguished from pernicious anemia by the absence of any effect of intrinsic factor. A similar pattern to that found in sprue is observed in patients with other intestinal disorders (Table 14-3, categories I-D through I-I). The values in Table 14-6 should be considered as examples only. Expected ranges will vary with the oral dose of labeled vitamin, the number of injections of "cold" vitamin, and the length of time over which urine has been collected.<sup>324</sup>

The most important source of error in the urinary excretion test is an incomplete urine collection. Another potential error is intro-

**Table 14-6. The Schilling Urinary Excretion Test of Vitamin  $B_{12}$  Absorption<sup>336</sup>**

Subjects	Urinary Excretion of Radioactive Vitamin $B_{12}$ * (%)	
	$B_{12}$ Given Alone	$B_{12}$ Given with Intrinsic Factor
Normal	18 (9-36)	—
Pernicious anemia	0.5 (0-1.2)	13 (6-31)
Non tropical sprue	3.6 (0-19)	3.3 (0-10)

\*Vitamin  $B_{12}$  dose 0.5  $\mu\text{g}$ . Urinary excretion varies with dose used as well as with other technical factors (see text)

duced by the presence of renal disease, which may delay complete excretion for as long as 72 hours. Because of these potential errors, it is useful to supplement the urinary excretion data with measurements made on plasma. Eight hours after the oral dose, 0.3 to 2.4% of the dose per liter of plasma is found in normal subjects, 0.4 to 2.24% per liter in uremic subjects, and only 0.02 to 0.15% per liter in patients with pernicious anemia. In patients with pernicious anemia given intrinsic factor the plasma level increases to 0.22 to 0.6% per liter.<sup>316</sup>

An additional disadvantage of the Schilling test is that the large parenteral dose eliminates the possibility of a subsequent therapeutic trial.

### Diagnostic Approach to the Patient

When confronted with a diagnostic problem involving macrocytic anemia, the physi-

cian should first try to distinguish between megaloblastic and non-megaloblastic anemia (Fig. 14-9). The most useful steps for this purpose are morphologic examinations. A diagnosis of megaloblastic anemia can be made on the basis of the presence of hypersegmented neutrophils and oval macrocytes in the blood or of typical megaloblasts in the marrow. These features are absent in patients with non-megaloblastic, macrocytic anemia. In the latter, the macrocytes tend to be round and, often, thin. Polychromatophilia and reticulocytosis may be prominent.

The non-megaloblastic anemias can be divided into those characterized by an increased number of reticulocytes and those in which the reticulocytes are normal or decreased in number (Fig. 14-9). These disorders are discussed in detail in Chapters 19 and 20.

In most cases of megaloblastic anemia, a preliminary diagnosis can be proposed on the basis of evidence provided by the history and

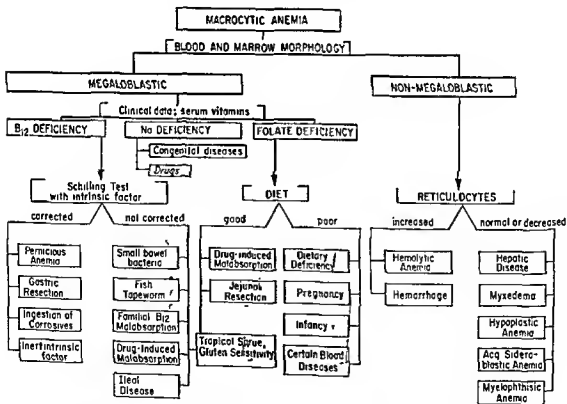

Fig 14-9 The approach to a diagnostic problem in macrocytic anemia. Closed boxes indicate findings, and open boxes represent procedures. (For discussion, see text.)

the physical examination. Particular attention should be paid to the patient's age, adequacy of diet, association with pregnancy, history of gastrointestinal operations, symptoms of steatorrhea, exposure to medications, alcoholism, family history, and the presence of neurologic disease.

Two common examples may be used to illustrate the usefulness of this kind of information. Megaloblastic anemia appearing in a previously healthy, well-nourished, elderly individual is most likely to result from pernicious anemia. On the other hand, the same type of anemia in a poorly nourished woman in her last trimester of pregnancy is almost certainly the consequence of folate deficiency.

For the difficult case, the sophisticated laboratory methods discussed above may be employed for precise diagnosis. The proper selection and interpretation of these tests depend upon the physician's careful analysis of the clinical data. In the above example of probable pernicious anemia, there is no need to obtain serum vitamin levels or to measure methylmalonate excretion. The diagnosis can be confirmed by measurement of vitamin B<sub>12</sub> absorption with and without added intrinsic factor.

Only in those patients with obscure or complex illnesses will a battery of biochemical procedures be required. In such circumstances, it is best to try to determine whether there is a deficiency of vitamin B<sub>12</sub>, of folate, or of neither (Fig. 14-9). There are no reliable morphologic criteria for this purpose. The detection of *subacute combined degeneration* of the spinal cord (see Chapter 15, page 606) is of importance because, with one possible exception,<sup>337</sup> this condition occurs only in vitamin B<sub>12</sub> deficiency; however, the absence of this sign is not helpful, since it now is an uncommon finding even in classical pernicious anemia.

Selection of appropriate laboratory methods to document vitamin deficiency depends to some extent on availability. Serum vitamin levels represent the most direct and reliable determinations for this purpose. If they are unavailable, it may be necessary to resort to therapeutic trial, as discussed in Chapter 13.

Vitamin B<sub>12</sub> deficiency states can be divided into those that are and those that are not due to absence of intrinsic factor, as indicated by the Schilling test (Fig. 14-9). Diagnosis of a folate deficiency state usually depends primarily on a carefully elicited history that includes information permitting critical evaluation of dietary intake (Fig. 14-9).

## Management

In most cases of megaloblastic anemia, the most important goal of therapy is the repletion of body stores of the deficient vitamin. Care should be taken to define the nature of the deficiency with precision so that the proper vitamin can be given in adequate amounts and over a sufficiently long period of time. To administer the wrong vitamin or a mixture of agents is not only wasteful and expensive, but also potentially dangerous. For example, therapeutic doses of folic acid may induce transient hematologic improvement in patients with vitamin B<sub>12</sub> deficiency, but the response is suboptimal, and, furthermore, the neurologic manifestations of vitamin B<sub>12</sub> deficiency may appear and progress during treatment.<sup>428</sup> Conversely, the folate-deficient patient may respond suboptimally to vitamin B<sub>12</sub>.<sup>347,460</sup>

In addition to therapy with vitamin B<sub>12</sub> or folate, it is sometimes possible to treat the underlying disease, eg, by surgical correction of anatomic lesions leading to small bowel bacterial overgrowth,<sup>311</sup> expulsion of the fish tapeworm,<sup>334</sup> discontinuation of drugs leading to vitamin malabsorption,<sup>118</sup> the use of a gluten-free diet in non-tropical sprue,<sup>275</sup> or by administration of antibiotics in tropical sprue.<sup>277</sup>

General measures appropriate to the treatment of all anemias have been discussed in Chapter 13 (page 550).

## Blood Transfusions

Transfusions are rarely required in megaloblastic anemia. Even when the anemia is severe, the likelihood of obtaining a dramatic response to specific therapy within 48 to 72

hours generally makes it unnecessary to subject the patient to the risks, discomfort, and expense of blood transfusion (Chapter 11). Sometimes, however, transfusion may be desirable and even life-saving. The most important indications for transfusion are signs of circulatory collapse, high-output cardiac failure with pulmonary congestion at rest, or severe or intractable angina. Mental deterioration is another indication, but a less definite one since this can be a manifestation of vitamin deficiency rather than cerebral anoxia. These situations must be treated as acute emergencies. In one series of 108 patients with megaloblastic anemia, the mortality rate was 14%, mostly because severe cardiac failure or myocardial infarction occurred before a therapeutic response was attained.<sup>47</sup>

While blood is being given, appropriate indicators of cardiac and circulatory function should be monitored frequently, including central venous or pulmonary wedge pressure. Fresh blood is to be preferred, to ensure optimal oxygen delivery capability (page 473). Only the packed red cells should be given. The rate of administration must be no greater than about 250 ml per four to six hours, and the patient should be kept in a sitting position. In unusually serious circumstances, "exchange transfusion" has been used, blood of low red cell content being removed from one arm while packed red cells are administered in the other.<sup>417-420</sup>

### *Therapy with Vitamin B<sub>12</sub>*

In 1926, Minot and Murphy demonstrated the value of liver therapy in pernicious anemia.<sup>433</sup> The induction of remission required the daily consumption of a half pound of liver, a regimen that severely tested the endurance of these patients! Desiccated whole hogs' stomach, mammalian kidney and brain,<sup>411,416</sup> and brewer's yeast,<sup>458</sup> all of which were shown to be effective remedies in this disease, are now only of historic interest. Even the highly effective, concentrated liver extracts that were developed in the 1930's now find no use.<sup>415</sup> Completely satisfactory results can be achieved by adminis-

tration of vitamin B<sub>12</sub>, which is both cheaper and less troublesome to administer than the older preparations.

**PREPARATIONS AND SIDE EFFECTS.** Two forms of vitamin B<sub>12</sub> are available for therapeutic use, namely, cyanocobalamin and hydroxocobalamin, the chemical structures of which are given in Chapter 4. Both are capable of inducing and maintaining remissions in vitamin B<sub>12</sub> deficiency states, and both are non-toxic except for very rare allergic reactions.<sup>430</sup> At high doses they differ in the degree to which they are retained in the body and excreted in the urine, as will be discussed below. Both forms of vitamin B<sub>12</sub> are available as solutions containing either 100 or 1000 µg/ml for intramuscular or subcutaneous use. Depot preparations, such as cyanocobalamin zinc tannate or cyanocobalamin-tannate in sesame oil-aluminum monosterate gel, have been marketed, but these offer no particular advantages over hydroxocobalamin.

**STORAGE AND EXCRETION.** The normal body stores of vitamin B<sub>12</sub> have been estimated to be between 3.5 and 11 mg (average 5 mg) (Chapter 4).<sup>414,415</sup>

In patients with signs of deficiency, stores have been estimated at 0.5 mg (0.1 to 0.7).<sup>403</sup> It is not possible to restore the normal body reserves by a single injection of vitamin B<sub>12</sub>, even if massive amounts are given, because only a portion of an injected dose is retained, and that amount is inversely related to the size of the dose. Of quantities up to 50 µg of cyanocobalamin, about 90 to 95% will be retained 48 hours after injection, but only about 45% of a 100-µg dose and only 15% of 1000-µg dose will be retained in the same period.<sup>402,412,414,431,435,438,443</sup> Most of the remainder is lost in the urine, principally during the first 24 hours after the injection.<sup>408</sup> Urinary losses continue at a moderate rate for another four to eight weeks before reaching a low, long-term rate of loss.<sup>407</sup> When hepatic disease is present the daily losses of cobalamin from body stores are about doubled. Even when as much as 5 mg of cyanocobalamin is given intravenously as a single

dose, only about 450  $\mu\text{g}$  remain in the body 10 days later.<sup>407</sup> If one or more mg of vitamin  $\text{B}_{12}$  are to be stored following parenteral administration, a number of injections separated from one another by at least 24 hours are required, rather than a single dose. Although large doses are not harmful, smaller doses allow more efficient conservation of the injected vitamin.

The amount of a larger dose that is retained depends upon the form of vitamin  $\text{B}_{12}$  that is injected. The initial retention of hydroxocobalamin is better than that of cyanocobalamin.<sup>410,422,442,449</sup> In the first 24 to 72 hours after injection, two to three times more hydroxocobalamin than cyanocobalamin is retained.<sup>402,408</sup> Twenty-eight days after the injection, although the amount of hydroxocobalamin retained has decreased by one fourth to one half, retention still is nearly three times greater than the retention of cyanocobalamin. After the fourth to eighth weeks, both cobalamins appear to be lost from the body at about the same rate (about 0.1 to 0.2% of body stores per day),<sup>401,407,450</sup> possibly because cyanocobalamin becomes converted to hydroxocobalamin *in vivo*.<sup>439</sup>

Despite the fact that, in the average patient, hydroxocobalamin provides higher serum concentrations of vitamin  $\text{B}_{12}$  for a longer period than does cyanocobalamin,<sup>410</sup> there is considerable individual variation in the duration of response. "Short responders" have been identified who do not maintain their serum  $\text{B}_{12}$  concentrations very well, no matter what compound is injected.<sup>449</sup> In these patients the serum  $\text{B}_{12}$  concentration may fall to 140 ng/l two weeks after hydroxocobalamin has been administered, about one eighth the time it takes for this to occur in the usual patient. Hematologic and neurologic relapses may occur when serum concentrations of vitamin  $\text{B}_{12}$  reach the neighborhood of 70 to 150 ng/l.<sup>403</sup>

**ROUTES OF ADMINISTRATION AND DOSAGE SCHEDULES.** Parenteral injections of as little as 1  $\mu\text{g}$ /day of vitamin  $\text{B}_{12}$  will induce a complete hematologic remission in pernicious anemia.<sup>447</sup> Doses of this size are recom-

mended when therapeutic trials are performed for diagnostic purposes (Chapter 13) because they will have no effect in folate-deficiency states. However, if vitamin  $\text{B}_{12}$  stores are to be replenished, considerably larger doses are required.

Recommendations regarding the compound, dose, and frequency with which vitamin  $\text{B}_{12}$  is injected for induction of remission, restoration of body stores, and maintenance of clinical remission vary. Although there is much latitude in therapy, it is necessary that the patient and his blood be examined frequently during the initial phase, in order to determine that remission is being achieved. Thereafter the patient should be examined every three to six months to make certain that remission is being maintained.

The following schedule has been used successfully for years as the initial treatment for pernicious anemia in relapse and for the reestablishment of body stores of vitamin  $\text{B}_{12}$ . Similar regimens may be employed for other vitamin  $\text{B}_{12}$  deficiency states. At first, 100  $\mu\text{g}$  of cyanocobalamin are given intramuscularly, daily, for six or seven days. Reticulocyte counts and simple clinical observations are made at the time of each injection. The characteristic clinical and reticulocyte response described below should occur within the week. If that is the case, the same amount is given on alternate days for another seven doses, and the hematocrit is measured twice weekly during that time. A distinct increase should be evident. After this, the injections are continued every third or fourth day for another two to three weeks, thereby providing a total of 1.8 to 2.0 mg  $\text{B}_{12}$  in five or six weeks. Such a schedule ensures that much of the administered  $\text{B}_{12}$  has been retained. By this time, hematologic values should have become normal.

Alternatively, only five weekly injections of 1 mg each of hydroxocobalamin are given,<sup>422</sup> depending on the desirability in the individual case for the patient to return for medical supervision. Early discovery of a patient's failure to respond promptly and completely allows a mistaken diagnosis to be recognized or interfering factors to be identi-

fied,<sup>447</sup> and corrective action may then be taken before further complications ensue.

Maintenance therapy with cyanocobalamin consists of monthly injections of 100  $\mu\text{g}$  for life. It is possible that the use of hydroxocobalamin may permit extension of the interval between injections,<sup>422,442,444</sup> although such a regimen might be a disservice to the "short responders" described in the previous section.<sup>449</sup> With hydroxocobalamin, 1.0 mg may be injected every two to four months and examinations made at least every four months to ascertain that the remission is being maintained. Alternatively, vitamin B<sub>12</sub> levels may be measured periodically to identify those patients who require frequent therapy.

Under exceptional circumstances, vitamin B<sub>12</sub> is given orally.<sup>431,433</sup> Candidates for oral therapy include patients who refuse parenteral injections or those in whom parenteral therapy may be hazardous, eg, when there is a coexisting disorder of hemostasis. Also, rare patients have been reported who exhibited hypersensitivity reactions to the vitamin when it was given parenterally, but not orally.<sup>421</sup> In pernicious anemia subjects, only about 1% of orally administered vitamin B<sub>12</sub> is absorbed, presumably by routes not dependent on intrinsic factor. Consequently, doses that are very large in relation to the body's requirements must be given, usually 300 to 1000  $\mu\text{g}/\text{day}$ . Another, considerably less satisfactory approach to oral therapy is the use of preparations containing vitamin B<sub>12</sub> and porcine intrinsic factor. Although this combination facilitates vitamin B<sub>12</sub> absorption at the outset, patients eventually become refractory to the action of such heterologous intrinsic factor because of the development of antibodies.<sup>405</sup> For this reason, and also because of greatly increased cost, these preparations have no legitimate therapeutic uses.

Patients receiving vitamin B<sub>12</sub> orally should receive closer supervision than those who receive the vitamin parenterally.<sup>431</sup> In all patients, the risk of hematologic and neurologic relapse, because of forgotten or otherwise omitted treatment, is ever present.

## Therapy with Folates

The first use of preparations containing folates was in the early 1930's when Wills and her colleagues found that the megaloblastic anemia of pregnant, Indian women responded to autolyzed yeast (marmite), or to a component of crude liver extracts that could be distinguished from the anti-pernicious anemia principle.<sup>456</sup> When crystalline folic acid became available in 1945 it almost entirely replaced the crude substances that were formerly used.

**PREPARATIONS.** The form of folate most commonly used for therapy is pteroylmonoglutamic acid, also known as folic acid. Prior to 1971, the standard oral folic acid tablet contained 5 mg, an amount that is not only excessive, but also wasteful since much of it is excreted. Presently available in the United States are tablets of 1.0, 0.15, and 0.1 mg. Folic acid is also available in a solution of 5 mg/ml for parenteral use. *Folinic acid* (N<sup>5</sup>-formyltetrahydrofolic acid) is available in solutions intended for parenteral use. Recent studies indicate that it may also be effective when given by mouth.<sup>436</sup>

**ABSORPTION, STORAGE, AND EXCRETION.** The normal body folate stores have been estimated at 5 to 10 mg, an amount sufficient for only about two to four months of normal hematopoiesis.<sup>40</sup> Stores of this magnitude can be maintained in normal subjects by a dietary intake of 50 to 100  $\mu\text{g}/\text{day}$ . The folates normally found in foodstuffs are polyglutamates and must be converted to the monoglutamate prior to absorption (Chapter 4). This conversion may be defective in many of the folate deficiency states, especially those associated with certain drugs and with malabsorptive disorders. On the other hand, the absorption of pteroylmonoglutamic acid in patients with these disorders may be normal or nearly so.

In normal subjects, approximately 80% (range 40 to 95%) of orally administered folic acid is absorbed, regardless of dose.<sup>404</sup> When folic acid is administered in doses less than 200  $\mu\text{g}$  per day, little or none is lost in the

urine. At higher doses, urinary losses are considerable. About 6% of a 1-mg dose, 10% of 2-mg, 50% of 5-mg, and 80% of 15-mg are excreted.<sup>23,413</sup>

**DOSES AND ROUTES.** An optimal hematologic response will occur if 50 to 100  $\mu$ g of folic acid are given daily by mouth. Such doses are useful for therapeutic trials (Chapter 13). However, for replenishment of stores, larger amounts are required. A daily dose of 1 mg for two to three weeks should be ample, even in patients with malabsorption. It is most unlikely that a patient who fails to respond to oral administration will respond to injections. The parenteral forms are useful chiefly in patients who are unable to take medications by mouth.

Once stores have been repleted, the need for maintenance therapy must be considered in the light of the underlying condition that produced the folate deficiency. If that condition can be corrected, normal dietary sources of folate should suffice. When the causative condition cannot be reversed, eg, when requirements are increased owing to a persisting severe hemolytic anemia or in pregnancy, when malabsorption cannot be corrected, as by a gluten-free diet, or when dietary habits are inadequate and immutable, appropriate supplements in the range of 0.1 to 0.5 mg daily must be given. The usual "prophylactic" dose in pregnancy is 0.3 mg/day. When the continued administration of diphenylhydantoin is necessary, 0.6 to 1 mg of oral folic acid daily may be required. Life-long therapy with folate is rarely necessary, but, if it is contemplated, vitamin B<sub>12</sub> absorption must be known to be normal (see below).

*Folinic acid* is the preparation of choice for the treatment of toxicity caused by folate antagonists. These agents inhibit the reduction of folic acid by dihydrofolate reductase. Folinic acid, being already fully reduced, bypasses this metabolic block. The usual dose is 3 to 6 mg given intramuscularly. Folinic acid also has been employed successfully in patients with congenital dihydrofolate reductase deficiency.<sup>304</sup>

**UNTOWARD EFFECTS.** Folic acid is remarkably free of toxic effects, except for very rare instances of allergic reactions.<sup>459</sup> In some epileptics, the frequency of seizures appears to have been aggravated by folate.<sup>411</sup>

By far the most important contraindication to folic acid therapy is the presence of an untreated deficiency of vitamin B<sub>12</sub>. As previously noted, a suboptimal hematologic response to folate may occur in such situations, but neurologic disease is not relieved, and, in fact, may appear and progress.<sup>428</sup> Of equal concern is the possibility that vitamin B<sub>12</sub> deficiency will develop at a later time during a long course of folate therapy. In this situation, hematologic manifestations may not develop and only neurologic disease will appear. It is therefore prudent, whenever possible, to perform tests of vitamin B<sub>12</sub> absorption whenever long-term folate therapy is contemplated. If absorption is defective, prophylactic vitamin B<sub>12</sub> therapy is justified.

#### *Response to Treatment with Vitamin B<sub>12</sub> or Folate*

In general, those aspects of disease that can be ascribed to vitamin deficiency are rapidly corrected by vitamin B<sub>12</sub> or folate therapy, but signs and symptoms of the underlying disease are not relieved. For example, in pernicious anemia, there is no regeneration of gastric cells; achlorhydria and other aspects of achylia gastrica are unchanged; and vitamin B<sub>12</sub> absorption remains profoundly impaired.

**SYMPTOMS.** Symptomatic improvement often may be recognized before any change in the blood is noticeable. The patient becomes more alert, more cooperative, and his appetite improves. These signs may be observed within 48 hours of adequate parenteral therapy. If soreness of the tongue is present, it also is usually relieved within 48 hours; regeneration of the papillae is observed within four to seven days, and the tongue becomes normal after two to three weeks.<sup>440</sup>

**BLOOD.** An increase in reticulocytes is the earliest and most useful sign of hematologic

**Table 14-7. The Relation of Reticulocyte Count at Its Peak to the Degree of Anemia in Patients with Pernicious Anemia Treated with Vitamin B<sub>12</sub><sup>23</sup>**

Initial Red Cell Count (cells $\times 10^{12}/l$ )	Reticulocytes at Peak (%)
<1.0	50-70+
1.0-1.49	36-47
1.5-1.99	25-34
2.0-2.49	15-22
2.5-2.9	10-16
3.0-3.6	4-9

response to therapy. With optimal therapy, the increase becomes apparent after two or three days and maximum numbers are reached on day five to eight. The magnitude of the reticulocytosis is related to the degree of anemia (Table 14-7). After the peak reticulocyte response has been reached, there is a gradual fall that may sometimes be interrupted by a second rise (Fig. 14-10). Nucleated red corpuscles may appear in the blood when the reticulocyte response occurs.

After a delay of about five to seven days, a perceptible increase in the VPRC is observed. The rate of increase is greatest in those patients with the most severe anemia (Fig. 14-11). If no complications develop, normal values should be attained by four to eight weeks, regardless of the initial degree of anemia.<sup>427</sup> Mean corpuscular volume, after a preliminary increase due to the increased numbers of reticulocytes,<sup>457</sup> gradually decreases (Fig. 14-10) and values return to normal at about the same rate as the red cell count becomes normal. Simultaneously, the marked anisocytosis decreases and the numerous bizarrely shaped erythrocytes disappear.

The neutrophilic leukocytes increase in number, usually reaching normal values within a week. Immature white cells may accompany the increase; myelocytes and even a rare myeloblast may be found. In rare instances, the temporary "shift to the left" may be so pronounced that the blood picture of myelocytic leukemia is simulated.<sup>418</sup> Hypersegmented leukocytes gradually disappear and usually are absent by 14 days.<sup>23</sup> The

**Fig. 14-10.** Variations in mean volume of red corpuscles compared with reticulocyte count in three patients with pernicious anemia. The mean corpuscular volume (CV) and the red cell count (RBC) are represented as percent of their respective average normal values. By this method the red cell count and mean corpuscular volume of a hypothetical normal individual would fall on the line at 100%. Reticulocytes are recorded directly. The abscissa records days following the commencement of liver therapy (From Wintrobe,<sup>26</sup> courtesy of Journal of Clinical Investigation.)

Fig. 14-11 Expected course of the VPRC (PCV) after the intramuscular administration of vitamin  $B_{12}$  to patients with pernicious anemia. There always is a lag averaging 1.98 days ( $t_0$ ) before a perceptible increase occurs. Ultimately an average VPRC value of 0.467 l/l ( $\lambda$  46.7) is reached. (From Waelsch and Sidak,<sup>452</sup> courtesy of the authors and *Folia Haematologica*.)

platelet count returns to normal within a week.<sup>437</sup>

If therapy is suboptimal or if complicating disease, eg, infection, is present, the typical response will be impaired.<sup>23</sup> In particular, the magnitude of the reticulocytosis will be reduced and the time at which peak values are reached will be delayed. The increase in VPRC also will be less rapid.

**BONE MARROW.** Following effective therapy, the morphologic appearance of the bone marrow is altered with extraordinary rapidity. Within six to ten hours, the number of megaloblasts may become greatly decreased.<sup>416</sup> By 24 to 48 hours, erythrocyte maturation is normoblastic.<sup>445</sup> The effect of therapy on individual megaloblasts has been disputed. It has been proposed that these abnormal cells can be converted directly to normal ones by supplying the missing vita-

min. On the other hand, sequential kinetic studies have suggested that the marrow is repopulated by an entirely new series of normoblasts from the stem cell level, and that the remaining megaloblasts are destroyed within the marrow.<sup>426</sup> Giant metamyelocytes may not disappear from the marrow for a week or more.<sup>23</sup>

**BIOCHEMICAL CHANGES.** The increased plasma iron concentration characteristic of megaloblastic anemia in relapse decreases over a 24- to 48-hour period. Distinctly subnormal levels may be reached.<sup>424</sup> The serum iron may remain low for several weeks. In patients with treated vitamin  $B_{12}$  deficiency, a similar pattern has been observed in serum folate levels; during the first 24 hours of therapy, a decrease from an average of 15.4 to 5.5 mg/l was observed, followed by a gradual increase over the next two weeks.<sup>454</sup>

Increased urinary methylmalonate levels (page 586) decrease in 48 hours and return to normal within a week.

The plasma bilirubin falls at about the end of the first week and usually will be found within normal limits at the end of three or four weeks. Urinary urobilinogen begins to decrease at the end of the reticulocyte response.<sup>419,425</sup> Free erythrocyte protoporphyrin tends to increase with therapy.<sup>435</sup> Megaloblastic bone marrow was found to contain no protoporphyrin,<sup>443</sup> but, with the re-appearance of normoblasts following therapy, protoporphyrin was detected in marrow and its quantity increased until the maximum reticulocyte value was reached; thereafter, the marrow protoporphyrin decreased slightly.

The serum urate level increases as reticulocytosis occurs, presumably because of accelerated turnover of DNA in rapidly proliferating erythrocyte precursors.<sup>409</sup> The increase may be prevented by the administration of the xanthine oxidase inhibitor, allopurinol. Urinary phosphorus decreases rapidly when the appropriate vitamin is first given, increases during reticulocytosis, and then gradually returns to normal values.<sup>429</sup> These changes probably are related to increased phosphorus uptake in association with the formation of increased quantities of cellular nucleotides and polynucleotides.

Serum potassium concentration falls an average of 0.9 mEq/l during the first 48 hours of therapy and then gradually returns to normal over the next several weeks.<sup>47</sup>

Serum LDH levels return to normal within one to two weeks.

**NEUROLOGIC MANIFESTATIONS.** Although progression of the neurologic disease in pernicious anemia is halted by vitamin B<sub>12</sub> therapy, the degree to which established lesions can be reversed varies. In general, the shorter the duration of the sign or symptom, the more likely it is to disappear with treatment; neurologic manifestations that have been present less than three months are usually reversible.<sup>405</sup> Symptoms of long duration may be lessened by treatment, but some residual dysfunction is to be expected. Neurologic improvement tends to be relatively

slow. Often six months or more elapse before a maximum response is achieved. As a rule of thumb, manifestations persisting after a year of optimal therapy may be considered irreversible. In a series of 44 patients with subacute combined degeneration, most of the observed neurologic abnormalities returned to normal or improved in 80 to 90% of patients.<sup>451</sup>

## Pernicious Anemia

History  
Incidence  
Etiology and Pathogenesis  
Clinical Manifestations  
Laboratory Findings  
Course, Prognosis, and Complications  
Pathology

**P**ERNICIOUS anemia is a chronic illness resulting from the lack of Castle's "intrinsic factor" in gastric secretions. In the absence of this gastric binding protein, absorption of vitamin B<sub>12</sub> is markedly impaired, and deficiency of the vitamin ultimately supervenes. The disease occurs in two forms: a relatively common adult type and a rare congenital variety. In the adult type, the lack of intrinsic factor is associated with gastric atrophy and deficiency of many other gastric secretions (achylia gastrica). In the congenital form, only intrinsic factor is lacking, other components of gastric juice remaining normal.

### History

The first (1855) clinical description of pernicious anemia is usually attributed to Thomas Addison,<sup>1</sup> but probable cases were recorded in 1823 by Combe and Andral, and in 1837 by Marshall Hall.<sup>2</sup> In his somewhat vague description, Addison used the term "idiopathic anemia," indicating that the diagnosis was made by excluding other, known

causes of anemia.<sup>1</sup> The term "pernicioser" was used by Biermer,<sup>2</sup> but, ironically, probably only one of his 15 patients had vitamin B<sub>12</sub> deficiency.<sup>3,12</sup> The anglicized version of Biermer's designation became popular after the term appeared in an 1876 editorial in an English medical journal.<sup>3,8</sup>

Even as early as 1860, Austin Flint expressed the view that "Addisonian anemia" results from deficient gastric secretions and consequent inadequate assimilation of food.<sup>9</sup> In 1870, Fenwick reported an autopsy study of a person whose gastric glands were found to be atrophic; the acidified mucosal scrapings failed to digest egg white.<sup>10</sup> Although achylia gastrica then came to be recognized as a consistent finding, and one which antedates the development of anemia, the pathogenetic significance of the observation remained a mystery.

Fifty years later, Whipple, while seeking to determine the antianemic effectiveness of various foods (Chapter 13), demonstrated the value of liver.<sup>11</sup> His observations led Minor and Murphy to embark on a therapeutic trial of giving large amounts of liver by mouth to patients with pernicious anemia. They reported in 1926 that the anemia could be promptly relieved by this regimen.<sup>13</sup> Before this, patients with pernicious anemia had been treated with an "iron-rich" diet—based on Whipple's observation—that contained liver,<sup>11</sup> and "liver soup" had been used in the treatment of tropical sprue. However, the

unique value of liver had not been appreciated before Minot and Murphy conducted their systematic study. The daily measurement of reticulocytes before therapy and the demonstration of a striking reticulocyte response associated with the feeding of liver made Minot and Murphy's findings convincing.

The investigations of Whipple and his associates, and those of Minot and of his pupil, William Castle, transformed hematology from a field concerned solely with morphology to the dynamic discipline it is today.<sup>4</sup> As will be discussed later (page 604), Castle's experiments clarified the relationship between achylia gastrica and the effectiveness of liver.<sup>3,6</sup>

## Incidence

### (i) Race

The adult form of pernicious anemia is particularly common among individuals of Scandinavian, English, and Irish ancestry<sup>26</sup> (Fig. 15-1). In such high-risk groups, about nine new cases are detected per 100,000 population per year, and about 0.13% of the population is affected.<sup>33</sup> The disease appears to be much less common in Caucasians of Italian or Greek origin.<sup>26</sup> Although once thought to be rare among American Indians, pernicious anemia was found to be as common among members of 10 Southwestern tribes as it is in Caucasians.<sup>34</sup> In studies of

Fig 15-1. Prevalence of pernicious anemia in natives of various countries, as indicated by 500 admissions from 1913 to 1932 to the Peter Bent Brigham Hospital, Boston. The values in percent indicate the proportion of cases of pernicious anemia among the total admissions from the various countries (From Friedlander,<sup>26</sup> courtesy of the author and American Journal of Medical Sciences.)

hospitalized patients, its prevalence in American Negroes was found to be about one third (Fig. 15-2) to one half of that in Caucasians.<sup>27</sup> It has been reported, albeit rarely, in the South African Bantu,<sup>31</sup> in Orientals,<sup>22,25,29</sup> and in Arabs.<sup>21</sup>

### Sex

A clear female preponderance has been observed in Great Britain and Scandinavia (1.7 to 2.0:1 or greater).<sup>23</sup> More nearly equal distribution between the sexes has been observed in the United States, and, in one large series, there was a slight male preponderance (Fig. 15-2).

Fig 15-2 Age, sex, and race of 329 patients with pernicious anemia admitted to the Johns Hopkins Hospital from 1925 to 1940. Negro patients of both sexes are represented together in the black portion of each column, white men are indicated by the hatched portion of each column, white women by the open portion. The height of each column represents the total number of patients of each age group. There were 171 white men, 125 white women, and a total of 33 Negroes, of which 20 were men and 13 women. The ratio of all white to Negro admissions at this hospital was about 3 to 1.

Fig 15-3. Incidence of pernicious anemia at various ages calculated according to number of cases per 100 000 population. Females hatched columns; males open columns. (From data for Sweden collected by Nordenson et al.<sup>32</sup>)

### Age

Pernicious anemia is most common in persons in late adult life. It is rare in individuals younger than 30 years of age and increases in frequency as age advances (Fig. 15-3). The average age of onset in one large series was 60.5 years.<sup>207</sup> In 1944, only four persons less than 20 years old were found among a total of 1532 pernicious anemia patients.<sup>24</sup> Since then, more cases in children have been reported. These appear to fall into two groups.<sup>30,25</sup> The illness in one group (about 27 patients) is designated "congenital" pernicious anemia, because it is usually apparent before the subject is two years of age. It is characterized by a lack of intrinsic factor, but the structure and function of the gastric mucosa are otherwise normal. In the second, even smaller group, having so-called "juvenile" pernicious anemia, onset has occurred in the second decade of life. Gastric atrophy is found and the illness seems to be the same in all respects as the adult disease.

### Etiology and Pathogenesis

Castle and his associates showed that a hematologic response in pernicious anemia could be achieved by administering beef

muscle previously incubated with normal human gastric juice, but that neither the beef nor the gastric juice was effective alone.<sup>6</sup> As a result of these experiments, Castle proposed that beef contains an essential "extrinsic factor" which combines with gastric "intrinsic factor" to form an antianemic principle that is stored in the liver. When vitamin B<sub>12</sub> was isolated, it was shown that this vitamin is both the extrinsic factor and the antianemic principle, and that gastric "intrinsic factor" is a binding protein essential to vitamin B<sub>12</sub> absorption. The metabolism of vitamin B<sub>12</sub> and the action of "intrinsic factor" have been discussed in Chapter 4.

In adult pernicious anemia, the fundamental defect is severe gastric atrophy with loss or extreme deficiency of all gastric secretions, including Castle's intrinsic factor. The cause of the gastric lesion remains unknown and continues to be the subject of active investigation. It is likely that inherited factors play a role in the illness, but the relatively late age at which the onset occurs and the lack of a clear hereditary pattern suggest that acquired, environmental influences must interact with the genetic defect.<sup>145</sup> Among the acquired factors is simple gastritis, a usually asymptomatic disease that appears to be extremely common and tends to progress with age. Also, immunologic mechanisms have been implicated in pernicious anemia by its association with certain "autoimmune" disorders and by the presence of antibodies directed against gastric antigens. Each of these topics will be discussed below.

### Genetic Factors

It seems clear that the congenital form of pernicious anemia is inherited, probably as an autosomal recessive trait.<sup>30,35</sup> Observations supporting these conclusions are: (1) the early age of onset, (2) a high incidence of consanguinity among the parents, and (3) the frequency with which siblings have been affected (10 of 27 families). There is no good evidence, however, of a genetic relation between the congenital and adult forms of pernicious anemia. With one exception, no in-

stances of adult pernicious anemia have been reported in families of patients with congenital pernicious anemia.<sup>35</sup> Furthermore, congenital pernicious anemia has not occurred in any members of the 15 reported families in which both parents had the adult form of the disease.<sup>23</sup>

Compilation of various studies of the familial incidence of adult pernicious anemia indicates that, within the families of 2246 patients, multiple occurrences of pernicious anemia could be demonstrated in 286 instances (12.7%).<sup>23</sup> In these studies, the proportion of families with more than one case of pernicious anemia ranged from 7.9%<sup>139</sup> to 30%.<sup>129</sup> It is possible that the higher figures are the more accurate ones, since they represented more thorough studies and included persons in older age groups.

It follows that the risk of developing the disease in relatives of patients with pernicious anemia is considerably greater than that of the general population. The overall prevalence of pernicious anemia among children, siblings, parents, and parent's siblings of patients with pernicious anemia is about 2.5%, or about 20 times the prevalence in the population at large.<sup>129</sup> The figure becomes even greater if age and closeness of relationship are considered. Of members of the highest-risk group (siblings), about 21% may be expected to acquire pernicious anemia before their ninetieth birthday.<sup>129</sup>

Eighteen instances of the concordant occurrence of pernicious anemia in twins have been reported<sup>105,114</sup>; however, in three other sets of twins the disease occurred in only one of each pair. These data appear to support a genetic origin for pernicious anemia. However, they must be interpreted with caution, for in many of the reports the evidence for the diagnosis or for the identity of the twins was inadequate.<sup>105</sup> Furthermore, even a single instance of failure of an identical twin to acquire his sibling's disease emphasizes the importance of nongenetic factors.

Also cited in support of a genetic origin for pernicious anemia is an increased incidence of some features of the disease in relatives. For example, in one study,<sup>109</sup> achlor-

Hydria was found in 27% of the relatives of patients with pernicious anemia. Although this incidence was not clearly different from that in age-matched controls, 8% (10 of 124) of the achlorhydric relatives were found to have both impaired vitamin B<sub>12</sub> absorption and reduced serum levels of the vitamin. In another investigation, partial defects in vitamin B<sub>12</sub> absorption, as measured by the Schilling test, were reported in relatives of pernicious anemia subjects.<sup>128</sup> However, according to a later study, inadequate urine collection may have been responsible for this finding.<sup>127</sup>

More convincing is the evidence that relatives of pernicious anemia patients are predisposed toward the production of autoantibodies to gastric parietal cells (see below). If the results of several series are combined, of 763 relatives examined, 24% (30% of the women and 18% of the men) were found to have circulating parietal cell antibodies.<sup>23</sup> The sera of only 3.8% of subjects in the control series gave positive evidence of the presence of these antibodies. In relatives of pernicious anemia patients, there may also be an increased incidence of certain diseases that occur with increased frequency in patients with pernicious anemia (page 608).<sup>145</sup>

Despite these studies, the pattern of inheritance remains in doubt. Both dominant and recessive modes have been suggested, but the incomplete penetrance of the trait has precluded rigorous proof of either. The nature of the genetic lesion remains unknown, but two major possibilities have been suggested<sup>113</sup>: (1) that it is a defect in immunologic tolerance to a particular group of antigens found in the stomach, thyroid gland, pancreas, and skin; and (2) that it is a defect in a metabolic or enzyme system common to these tissues.

It has been suggested that adult pernicious anemia may exist in two forms, inherited and acquired.<sup>120</sup> According to this hypothesis, in contrast to the acquired form the inherited form is characterized by (1) an earlier age of onset (average 51 vs. 66 years), (2) a characteristic association with certain other diseases (page 608), and (3) somewhat lower serum immunoglobulin levels.

## Gastritis

A high proportion of otherwise normal individuals over the age of 30 have been found to have histologic evidence of gastritis on gastric biopsy.<sup>121</sup> Both the incidence and the severity of gastritis increase with age (Fig. 15-4). At least three histologic stages of progression have been defined: (1) superficial gastritis, (2) atrophic gastritis, and (3) gastric atrophy. In the last two stages, glandular structures are destroyed, and there is a progressive loss of gastric secretions. Characteristically, hydrochloric acid, pepsin, and intrinsic factor are lost in that order.<sup>15</sup> Patients with severe degrees of atrophic gastritis or with gastric atrophy may develop impaired vitamin B<sub>12</sub> absorption.<sup>23</sup>

These forms of gastritis usually are asymptomatic.<sup>124</sup> The causes,<sup>115</sup> which are multiple and incompletely understood, may include (1) chemical, thermal, and mechanical injury to the mucosa, (2) nutritional deficiency (iron, folate, ascorbate), (3) endocrinologic insufficiency (thyroid, adrenal, pancreatic), (4) genetic abnormalities, and (5) autoimmune mechanisms, as discussed below.

The relation of the gastritis to pernicious anemia continues to be debated. Gastric biopsy in patients with pernicious anemia may demonstrate either gastric atrophy or severe atrophic gastritis.<sup>115</sup> Two possibilities must be considered. (1) that pernicious anemia represents the end-point of progressive gastritis, and (2) that the genetic lesion of pernicious anemia interacts with the gastric disorder to produce pernicious anemia. As noted above, both of these may be correct, leading to two types of pernicious anemia, "inherited" and "acquired."<sup>120</sup> According to a prospective study, simple atrophic gastritis did not appear to progress to overt pernicious anemia.<sup>138</sup>

## Immunologic Mechanisms

### Circulating Antibodies

In the sera of patients with pernicious anemia, several antibodies that react with human tissue antigens have been described

Fig 15-4 Prevalence of gastritis by age in the general population as determined by gastric biopsy (Prepared from the data of R A Joske<sup>121</sup>)

(Table 15-1). These have been called *auto-antibodies* because they appear to be directed against the tissues of the host. The most frequently found antibody reacts with antigens in the cytoplasm of *gastric parietal cells* and is detected by either a complement-fixation or immunofluorescent technique.<sup>111</sup> This antibody may also be found in a small proportion of apparently "normal" subjects (who probably have asymptomatic gastritis, see Fig. 15-4) and in about half of those known to have gastritis (Table 15-1).

*Antibodies to intrinsic factor* are detected less frequently, but are more specific since, with very rare exceptions,<sup>134</sup> they have been found only in pernicious anemia patients (Table 15-1). Intrinsic factor antibodies are of two types.<sup>136,137</sup> The more common are the so-called "blocking" antibodies, which prevent vitamin B<sub>12</sub> from complexing with intrinsic factor and are therefore presumed to react at or near the B<sub>12</sub> binding site. The less common, "binding" (or "precipitating") antibodies, which are rarely found in the absence of blocking antibodies, bind either intrinsic factor alone or the intrinsic factor-B<sub>12</sub> complex and presumably react with a part of the molecule not required for B<sub>12</sub> attachment. Intrinsic factor antibodies may be detected by

several techniques, including radioimmunoassay.<sup>135</sup> After intrinsic factor antibodies have been complexed with intrinsic factor, they may be separated from parietal-cell antibodies by gel filtration.<sup>122</sup> All of these serum antibodies belong to the IgG class of immunoglobulins. They are heterogeneous with respect to light-chain composition, indicating that they are not produced by a single clone of cells and probably represent a normal immunologic response to antigenic stimulation.<sup>108</sup>

Circulating cytotoxic antibodies directed against lymphocytes have also been found in pernicious anemia subjects.<sup>118</sup> Their significance is unknown, but they also occur in persons with other "autoimmune disorders" such as lupus erythematosus and rheumatoid arthritis.

Antibodies also have been found in the gastric juice,<sup>117,132</sup> where they may be either of the IgG or of the secretory IgA type, the latter indicating an origin within the stomach itself.<sup>117</sup> Formation of autoantibodies by cells within the gastric mucosa also was suggested by an immunofluorescence technique.<sup>107</sup> Gastric juice antibodies may be difficult to detect because they are often complexed with intrinsic factor.<sup>132</sup> They may occur in the

absence of a corresponding serum antibody.<sup>111,133</sup>

Also found in patients with pernicious anemia and their relatives are complement-fixing antibodies to thyroid acinar cytoplasm<sup>112</sup> (Table 15-1).

### Cellular Immunity

In addition to the humoral antibodies, phenomena typical of cell-mediated immune mechanisms may occur in pernicious anemia subjects. In one study, lymphocyte transformation was observed when lymphocytes from 3.4 to 37.5% (depending on the antigen used in the test) of patients with pernicious anemia were exposed to various gastric antigens.<sup>110</sup> In other studies, leukocyte migration has been inhibited by intrinsic factor or other gastric antigens in patients with overt pernicious anemia.<sup>112,131</sup>

### Association of Pernicious Anemia with Certain, Possibly "Autoimmune," Disorders

In patients with pernicious anemia the incidence of thyroid disease is comparatively high<sup>101</sup> (Table 15-2) and vitiligo also is common.<sup>121</sup> Diabetes is frequently associated with pernicious anemia, but, since diabetes is so common in the general population, a truly increased incidence in pernicious anemia subjects has been difficult to establish.<sup>23</sup> Two rare endocrinologic diseases have been reported in association with pernicious anemia often enough to suggest that the occurrence is greater than would be expected on the basis of chance alone; namely, Addison's adrenal atrophy (20 cases) and idiopathic hypoparathyroidism (17 cases).<sup>23</sup> In one study of 99 patients with pernicious anemia, the prevalence of rheumatoid arthritis (5 cases) was not significantly greater than in the control group; however, there was an increased prevalence (11 cases) of a positive reaction to the test for rheumatoid factor.<sup>113</sup> Coombs' positive hemolytic anemia has been observed infrequently.<sup>110,131</sup>

### Significance of the Autoimmune Phenomena

Whether the autoimmune manifestations in pernicious anemia are the result<sup>119</sup> or a cause<sup>23</sup> of the disease continues to be controversial.<sup>5</sup> It is possible that the inflammatory gastritis leads to release of tissue antigens followed by an appropriate antibody response. Also, the inflammation conceivably may alter normal tissue components so as to render them antigenic. Antibodies formed to such stimuli might not circulate at first because they would combine with the remaining normal antigens. With the antigen loss accompanying continued and progressive tissue destruction, the combining capacity would decrease, and measurable titers of the antibody would then appear. Thus the appearance in the circulation of intrinsic factor antibody, for example, might signify only that tissue levels of intrinsic factor were either lost or so depleted as to be insufficient to absorb the antibody. Such a sequence of events has its parallel in the appearance of antibodies to glomerular basement membrane after removal of kidneys afflicted with glomerulonephritis, and the disappearance of these antibodies when renal grafting is performed.<sup>5</sup>

Possible pathogenetic actions of the humoral and cellular antibodies include: (1) damage to cells and/or induction or aggravation of inflammatory gastritis and (2) inhibition of vitamin B<sub>12</sub> absorption. As yet, no inflammatory or cytotoxic activity has been demonstrated for either parietal-cell or intrinsic factor antibodies. However, it is possible that cell-mediated mechanisms are of greater importance in such reactions.<sup>112,130</sup> To some investigators, the histologic picture of the gastric lesion, especially the infiltration with lymphocytes and plasma cells, suggests immunologic inflammation and resembles that of the lesion of autoimmune (Hashimoto's) thyroiditis.<sup>111</sup>

Intrinsic factor antibodies may inhibit vitamin B<sub>12</sub> absorption if they are present in gastric juice,<sup>111</sup> but they appear to have little or no effect if they are confined to the circulation.<sup>125</sup> Thus, absorption of vitamin B<sub>12</sub>

**Table 15-1. Frequency of Autoantibodies in Patients with Pernicious Anemia and Other Disorders**<sup>23,111,123,134,143,144</sup>

Subjects		Frequency of Antibodies		
		to Parietal Cells	to Intrinsic Factor	to Thyroid Cytoplasm
Normal	Men under 55	5.6%	very rare	5.2%
	Men over 55	9.2%	<1%*	
	Women under 55	14.7%	very rare	12.2%
	Women over 55	22.3%	<1%*	17.8%

Relatives of patients with myxedema		20%	—	46%

\*Probably with latent pernicious anemia

given with excess hog intrinsic factor was normal (19.3%) in pernicious anemia patients lacking intrinsic factor antibodies, and was not significantly reduced in those with serum antibodies only. However, absorption was clearly reduced in patients with antibodies in gastric juice only or in those with antibodies in both gastric juice and serum (to 11.1% and 8.4%, respectively).<sup>133</sup> Further evidence for

an effect of gastric juice intrinsic factor antibody on absorption is the observation that porcine intrinsic factor is more effective than human intrinsic factor in facilitating vitamin B<sub>12</sub> absorption in patients with pernicious anemia.<sup>102</sup>

In three reports, the transplacental transfer of intrinsic factor antibodies was documented.<sup>106,110,116</sup> These studies presented an

**Table 15-2. Association between Pernicious Anemia and Certain Other Diseases**

Disease	Occurrence of Indicated Disease in		Occurrence of Pernicious Anemia in Patients with Indicated Disease
	Controls	Patients with Pernicious Anemia	
Diabetes mellitus	1.3–1.7%	2.4%	0.4%
Graves disease		1.8%	3.1%
Myxedema		2.4%	10.8%
Vitiligo	0.1%	1.6%	8% <sup>117</sup>

Combined data from a number of investigations, as summarized by Chanarin.<sup>23</sup>

opportunity to observe the effect of such antibodies on a normal infant. Intrinsic factor was present in the gastric juice of one of three infants and absent in the other two, one of whom became deficient in vitamin B<sub>12</sub> at age three months. All of 36 control infants were found to have intrinsic factor in their gastric juice. These observations suggest that a circulating antibody can sometimes, but not always, impair the secretion of gastric intrinsic factor.

Possibly bearing on the pathogenetic importance of the autoimmune phenomena is the effect of adrenal corticosteroids. These agents have been observed to bring about increased vitamin B<sub>12</sub> absorption and hematologic improvement in patients with pernicious anemia, but not in those with the megaloblastic anemia that follows gastrectomy.<sup>101,101</sup> This response sometimes, but not always, has been accompanied by histologic improvement in the gastric mucosa and by the appearance in gastric juice of hydrochloric acid and increased amounts of intrinsic factor. With steroid therapy, serum titers of intrinsic factor antibody decreased in 18 of 28 patients (64%)<sup>101</sup>; however, the enhanced vitamin B<sub>12</sub> absorption was observed both in patients with such serum antibodies and in those without. Furthermore, absorption often improved before any decrease in serum antibody titer was observed.<sup>103</sup> Few data are available regarding steroid-induced changes in gastric juice antibodies, in at least two subjects, such antibodies disappeared as vitamin B<sub>12</sub> absorption improved, but, in others, there was no demonstrated relation between the improved absorption and the presence or absence of gastric juice antibodies.<sup>101</sup> Thus, although effects on antibody synthesis or action seem the most attractive explanation for the influence of steroids, proof for this hypothesis is still wanting.

More than 20 patients have been described in whom pernicious anemia and adult-onset immunoglobulin deficiency coexisted.<sup>142</sup> In most of these patients, the immunoglobulin deficiency was apparent before the pernicious anemia was detected. The pernicious anemia

in these individuals was typical in every respect except for an early age of onset (mean, 34 years) and the absence of circulating antibodies to parietal cells, intrinsic factor, or thyroid tissue. This observation constitutes strong evidence that humoral antibodies are not necessary for the development of pernicious anemia. On the other hand, "auto-immune" disorders such as rheumatoid arthritis are relatively common in patients with immunoglobulin deficiency. In explanation of this apparent contradiction concerning the role of immunologic mechanisms in the pathogenesis of pernicious anemia, it has been suggested that cell-mediated immunologic mechanisms become exaggerated in immunoglobulin deficiency, and can then play a role in certain autoimmune phenomena, including the gastric atrophy of pernicious anemia.

## Clinical Manifestations

### Mode of Onset and Initial Symptoms

The onset of pernicious anemia is characteristically insidious, and by the time the patient seeks medical attention the anemia may be moderately severe. An average of 15 months was found to elapse from the onset of symptoms to diagnosis.<sup>207</sup> It is common to discover a degree of anemia that is much greater than suggested by the appearance of the patient or the severity of his symptoms. The chief exceptions to this rule are those patients in whom symptoms referable to the nervous system appear early and progress rapidly before anemia has become severe or has even developed. Also, soreness of the tongue may appear early, before anemia of an appreciable degree of severity is present.

The diagnostic triad of weakness, sore tongue, and paresthesias is the classic symptom complex at presentation, but the initial symptoms actually vary. Not infrequently they suggest the presence of some digestive disorder, or cardiac, renal, or genitourinary disease, or even mental aberration or obscure infection. In such instances, the underlying

**Table 15-3. Presenting Complaints in Pernicious Anemia<sup>207</sup>**

Symptoms of anemia	58%

Sore tongue or mouth ✓	7%
Weight loss ✓	5%
Difficulty in walking ✓	3%
Other ✓	3%

disease may not be suspected until the blood has been examined.

Initial complaints, in order of frequency, are listed in Table 15-3. Some of these may be found to have been present for a number of months, rarely for several years and, characteristically, have varied in their intensity from one time to another.

#### Outward Appearance of the Patient

When the anemia is severe, the skin has a delicate lemon-yellow tint resulting from the combination of pallor and mild icterus. The sclerae may be yellowish, but often the increased bilirubinemia detectable in the blood is barely manifested clinically. There may be diffuse or blotchy, brownish pigmentation<sup>202</sup> interspersed with patches of vitiligo.<sup>121</sup> The skin may be dry, but is often peculiarly velvety and smooth, yet inelastic. Petechiae are unusual.

It is remarkable how frequently patients suffering from this disease have blond or prematurely gray hair and light-colored eyes.<sup>205</sup> Often the face is wide and the chest is broad with a wide costal angle; however, there are many exceptions to these generalizations.

Weight loss, while often slight, may be considerable. The average weight loss in a series of 50 patients was 14 pounds.<sup>226</sup> As a rule, the loss can be explained on the basis of anorexia.

#### Body Temperature

Fever of several degrees is common when the anemia is severe and may occur in the

absence of infection. Unexplained fever was found in 22% of patients in one series.<sup>208</sup> Such fever disappears promptly following effective treatment.

#### Gastrointestinal System

An abnormal tongue is found in about half the patients with pernicious anemia, and is one of the classic manifestations of the disease.<sup>23</sup> Tongue symptoms may occur in the absence of anemia. Their appearance or re-appearance in pernicious anemia patients portends a relapse and, in patients under treatment, is an indication of inadequate therapy.

When glossitis is at its height, the tongue is very painful and "beefy" red. Its entire dorsum may be involved, or there may be red patches at the margins or on the dorsum. Rarely the entire mouth and throat may be involved, causing the patient to complain of burning and pain on swallowing. More frequently, there is only burning or soreness, particularly of the anterior half of the tongue.

The intensity of the glossitis usually subsides after several days, but the soreness often recurs at intervals of varying length. Between attacks, the epithelium of the tongue is left devoid of papillae, thus producing the smooth, glazed tongue that is characteristic of pernicious anemia (Fig. 15-5). Partial loss of taste may ensue. Some patients whose tongues are quite smooth deny ever having had sore tongues. Some restoration of the papillae often is associated with adequate therapy.<sup>219</sup>

Loss of appetite is a frequent complaint. In one large series, 65% had "poor" appetite, and in 14% the symptom was so severe that all desire for food was lost and the diet consisted only of fluids and small amounts of breads and cereals.<sup>207</sup>

The frequency of diarrhea as a manifestation of pernicious anemia varies greatly (7% to 50% of cases), but, even when frank diarrhea has not occurred, direct questioning frequently will bring out the fact that the patient has a semisolid bowel movement immediately on arising and another one or two stools later

Fig 15 5 Smooth tongue of patient with pernicious anemia

in the day, a pattern possibly associated with achlorhydria. In one series, however, constipation was more common than diarrhea.<sup>207</sup>

Less frequently, complaints referred to the gastrointestinal tract may suggest the presence of a large variety of diseases, including gallbladder or malignant disease, or peptic ulcer. Pseudotumors caused by hypertrophy of the musculature of the pylorus have been described.<sup>203,218</sup> There may be anorexia, nausea, "gas," a sense of fullness and epigastric discomfort, heartburn, vomiting, and irregular abdominal pain that varies in intensity. Attacks of paroxysmal pain resembling the gastric crisis of *tuberculous dorsalis* sometimes occur.<sup>201</sup> Such an attack may be associated with vomiting and some abdominal rigidity. It is rare, however, to observe attacks as severe as are often seen in patients with sickle cell anemia. In pernicious anemia the pain may be symptomatic of changes in the spinal cord.

The liver may be slightly enlarged. When congestive heart failure is associated with the anemia, the liver may be greatly enlarged and tender. At autopsy the spleen is found to be moderately enlarged in practically all subjects, but there is no agreement as how often it is palpable clinically. In one large series,

it was palpable in 19% of patients<sup>207</sup>; in others, the incidence ranged from 3% to 40%.<sup>204</sup> Pronounced enlargement is unusual. With adequate treatment, the liver and spleen recede behind the costal borders.

### Circulatory System

The cardiovascular symptoms of anemia were discussed in Chapter 13. In pernicious anemia, they may be so pronounced as to lead to a mistaken diagnosis of primary cardiovascular disease. Dyspnea, palpitation, sensations of extra beats, excessive weakness, vertigo, and tinnitus may be associated with signs of congestive cardiac failure, including well-marked edema and cardiac and hepatic enlargement. In other patients angina pectoris may develop.<sup>220</sup> Systolic murmurs at the base of the heart and even at the apex are often heard. Occasionally, a diastolic murmur at the aortic area, possibly due to dilatation of the aortic ring, is detected. Cardiac irregularity seldom occurs but tachycardia is common. The vessels in the neck may be seen to pulsate if the anemia is severe and a loud venous "hum" may be present.

### Genitourinary System

Occasionally the clinical picture of chronic nephritis may be simulated by pernicious anemia. The renal function, as measured by fixation of the specific gravity of the urine, may be impaired and small amounts of albumin and casts may be found.<sup>206</sup> However, the nonprotein nitrogen, blood urea nitrogen, or creatinine values are not often elevated. The renal defects generally decrease with subsidence of anemia.

In patients with severe neurologic disease, impaired micturition and urinary retention may occur. This may predispose to infectious complications, such as cystitis.

Infertility has occasionally been ascribed to pernicious anemia.<sup>214</sup>

### Nervous System<sup>220</sup>

At one time, complaints referable to the nervous system were encountered in as many

as 95% of pernicious anemia patients, and the degree of involvement was considered severe in about 30%.<sup>213,228</sup> As facilities for diagnosis and treatment have improved, serious neurologic manifestations have become less common than they once were.<sup>203</sup> It is now estimated that about 30% of patients experience relatively mild neurologic disturbances (especially paresthesias and minor cerebral symptoms) and that signs and symptoms of spinal cord involvement are detected in only about 7%.<sup>23</sup>

The degree of nervous system involvement does not correlate well with the degree of anemia. In exceptional cases, pronounced neuropathy is found in the absence of any hematologic abnormality.<sup>222</sup> In one series, the blood hemoglobin concentration was greater than 9 g/dl in 30% of patients with distinct spinal cord involvement.<sup>207</sup> Neurologic disease may progress while the hematologic manifestations are corrected by folate ingestion.<sup>209</sup>

The neurologic illness chiefly affects the white matter of the dorsal and lateral columns of the spinal cord and the cerebral cortex. Peripheral nerve degeneration also occurs,<sup>217,225</sup> but it is uncertain whether this represents a distinct lesion or a process secondary to spinal cord disease. Because multiple nerve pathways are involved, the terms "subacute combined degeneration" and "combined system disease" have been applied.

With the possible exception of minor cerebral disturbances (see below), subjective sen-

sory complaints constitute the earliest and most frequent evidence of nervous system involvement<sup>231</sup> (Table 15-4). Most commonly, the patient experiences symmetrical tingling or "pins-and-needles" sensations, first in the tips of the toes and later in a stocking-and-glove distribution in all four limbs. Less frequently, the abnormal sensations may be described as "numbness," "coldness," or "tightness." Least common of all are tabes-like shooting pains. When paresthesias are the only symptom, there may be little or no objective evidence of neurologic disease.

At a later stage, there is clearer evidence of dorsal column involvement. The patient may complain of clumsiness and his gait may be incoordinated and ataxic. Reduced vibration sense, especially at higher frequencies (eg, 256 cycles/sec), is one of the earliest objective signs. Position sense may be impaired. The most sensitive way of detecting this abnormality is by manipulation of the index toe. The reaction to the Romberg test may become abnormal.

The lateral columns (pyramidal tracts) become involved in the later and more severe stages of the illness. Weakness and a spastic or "scissors" gait may develop. The Babinski sign is the earliest and most reliable objective evidence of lateral column disease. Hyperreflexia and clonus also may be observed.

If minor manifestations are included, cerebral disturbances may be considered to be common in patients with pernicious anemia

Table 15-4. Neurologic Manifestations in Pernicious Anemia

	Symptoms	Physical Findings	Location of Lesions
Mild	Paresthesias	None or slight impairment of touch and temperature sensation	Peripheral nerves(?) Dorsal columns
Moderate	Weakness Unsteady gait Clumsiness	Decreased vibration and position sense Romberg sign	Dorsal columns
Severe	Severe weakness Spasticity	Hyperreflexia Clonus Babinski sign	Dorsal and lateral columns

in relapse. The first manifestations may be cerebral<sup>221</sup> and may antedate other signs of the disease.<sup>211,230</sup> In a controlled study, depression and impaired memory were frequent, but only the latter seemed clearly related to vitamin B<sub>12</sub> deficiency.<sup>227</sup> In another study,<sup>221</sup> in 13 out of 17 patients with hemoglobin levels of 6.0 g/dl or less there was a clinically demonstrable reduction in the level of consciousness, justifying the diagnosis of delirium. In this study the most valuable single test was the serial subtraction of numbers, such as 7 from 100. Electroencephalograms demonstrated slowing in wave frequency. Therapy was associated with improvement in the level of awareness and in the behavioral disturbances consequent to the reduced awareness, and, in most instances, reversion of electroencephalographic tracing to normal. Since improvement was observed to take place about the time the reticulocyte response began, it seems likely that the cerebral involvement is a metabolic one and not secondary to the anemia.

More serious mental changes, as indicated by delusions, hallucinations, manic outbursts, and paranoid and schizophrenic states ("megaloblastic madness"), are uncommon.<sup>215</sup> Such psychoses may be curable if treated promptly.

Less common neurologic manifestations of pernicious anemia include ophthalmoplegia,<sup>212</sup> atony of the bladder, impotence,<sup>216</sup> perversion or loss of the senses of taste and smell,<sup>223</sup> and retrobulbar neuritis.<sup>214</sup> The last may be aggravated or precipitated by the use of tobacco.<sup>210</sup>

## Laboratory Findings

### Blood and Bone Marrow

The hematologic abnormalities in megaloblastic anemia were presented in detail in Chapter 14 and in Figures 14-1, 14-2, 14-3, 14-4, and 14-5. Pernicious anemia, the prototype of the megaloblastic anemia group, exhibits all of the abnormalities discussed in that section. The degree of the various deviations from normal varies with the severity of the deficiency.

Prior to the availability of specific therapy, unusually severe degrees of anemia were reported in patients with pernicious anemia. Naegeli found a red blood cell count of  $0.138 \times 10^{12}/l$  in one of his patients,<sup>259</sup> and Zadek recorded  $0.086 \times 10^{12}/l$ .<sup>260</sup> In Cabot's 1908 series, 21% of patients had red cell counts of less than  $1.0 \times 10^{12}/l$ , whereas only 1% of a series of 250 patients collected between 1944 and 1956 had a similar degree of anemia.<sup>208</sup> Today, most patients seek medical attention when the VPRC is between 0.15 and 0.25  $l/l$  (Fig. 14-2).

### Gastrointestinal Secretions

The total volume of gastric secretion is markedly reduced, eg, to an average of 15 ml/hr,<sup>254</sup> which is about 10% of normal. Furthermore, no increase in volume of secretion occurs after administration of histamine.

Absence of hydrogen ion secretion (achlorhydria) with maximum histamine stimulation (40  $\mu$ g/kg body weight) is practically a universal finding. Hydrogen ion secretion may be said to have occurred when the pH falls by at least one unit and to a value below 6.0 with such stimulation. In patients with pernicious anemia, basal pH values are always greater than 6.0 and usually greater than 7.0.<sup>23</sup> When histamine is given, the pH often remains the same or increases. In a small proportion of these patients an insignificant fall (0.1 to 0.7 units) may be observed. Earlier studies on gastric acid usually employed Topfer's reagent, by means of which the presence of "free acid" was inferred by a red color (pH value less than about 3.5). Obviously, by this relatively insensitive technique, no "free acid" should be found either before or after histamine stimulation.

Prior to 1951, 61 (of a total of 4215) patients who were said to have pernicious anemia with "free acid" in their gastric juice had been reported.<sup>258</sup> No such cases have been reported since more specific methods for establishing the diagnosis (eg, the Schilling test) have become available. It is probable that in many of these patients the megaloblastic anemia was due to folate deficiency or

vitamin B<sub>12</sub> malabsorption resulting from factors other than from lack of intrinsic factor.<sup>23,252</sup> In only one instance was a lack of intrinsic factor demonstrated by bioassay in a patient whose gastric secretions contained free acid.<sup>253</sup>

The hallmark of pernicious anemia is the extreme deficiency of intrinsic factor in the gastric secretion. An intrinsic factor assay suitable for routine clinical purposes is not presently available. When gastric juice was assayed by an immunologic method, the normal stomach was found to secrete 2000 to 18,000 units of intrinsic factor in the hour following histamine (40 µg/kg) stimulation. When 41 patients with pernicious anemia were studied by the same technique no intrinsic factor could be detected in 24 of them and less than 150 units were secreted by the others.<sup>23,251</sup> It was estimated that about 500 units are required for normal vitamin B<sub>12</sub> absorption. Intrinsic factor secretion also was reduced in a proportion of patients presumed to have atrophic gastritis without pernicious anemia, but usually the values were greater than those found in pernicious anemia patients. Peculiarly, patients with gastritis appeared to absorb more vitamin B<sub>12</sub> at a given level of intrinsic factor secretion than did pernicious anemia patients,<sup>251</sup> perhaps reflecting in the latter interference with absorption by intrinsic factor antibodies.

Gastric juice pepsin is reduced in pernicious anemia, but pepsin is not commonly measured because it has little more significance than free acid and is somewhat more difficult to quantitate. Similarly, pepsinogen in urine<sup>256</sup> or serum<sup>257</sup> tends to be reduced, but neither determination is a dependable test for pernicious anemia.

Findings on gastric biopsy were discussed earlier (page 606).

Pancreatic enzymes have been found to be present in patients with pernicious anemia, but tryptic activity was decreased, especially in those with moderate or advanced nervous system involvement.<sup>255</sup>

The diagnosis, differential diagnosis, and management were discussed in Chapter 14.

## Course, Prognosis, and Complications

Prior to the introduction of effective therapy the outcome in a case of pernicious anemia was fatal. The mortality rate in hospitalized patients was 53% in the first month.<sup>316</sup> However, in many patients the course of disease was one of remissions and relapses of varying severity and duration until death occurred, usually in one to three years.<sup>315</sup> Some patients were known to live for as long as 14 or even 20 years.<sup>313</sup> In Cabot's large series, remissions occurred in 86%, and 15% of the subjects had more than two remissions. Some of the remissions followed blood transfusion, the administration of arsenic, or splenectomy, and probably some patients unwittingly took liver or other substances now known to have real therapeutic value. Competent clinicians insisted,<sup>302</sup> however, that spontaneous remissions that were not the result of the inadvertent ingestion of antianemic material did occur in the pre-liver era. In any event, remission was rarely complete, and neurologic involvement progressed. In the few patients reported to have recovered, the diagnosis must be held in doubt.

Present methods of treatment have completely changed the outlook in pernicious anemia. Since 1926 there has been a striking decrease in mortality from pernicious anemia in various countries.<sup>303,312,314,315</sup> All ages and both sexes have shown lower mortality. Despite this improvement, the early mortality remains disturbingly high—14% in one recent series—largely due to cardiac failure occurring before a therapeutic response could be achieved.<sup>307</sup>

The most important present-day cause of relapse is the patient's reluctance to continue treatment for life and his readiness when new complaints develop to attribute them to the treatment. It is common to find that a relapse followed the onset of some intercurrent disease or that the need for some surgical measure distracted attention from antianemic therapy and caused it to be neglected at a time when it was most needed.

How soon relapse will occur once therapy has been stopped is unpredictable in the individual case. This depends not only on the development of intercurrent diseases but also, in addition to possible unknown factors, on the quantity of vitamin B<sub>12</sub> that is stored within the body, the inadvertent consumption of food factors having therapeutic value in pernicious anemia, and the degree of intrinsic factor deficiency. In one study of 54 cases,<sup>311</sup> relapses were found to develop at intervals varying from two to 38 months after therapy was discontinued. In a third of the subjects these appeared during the first six months and in 36% during the second six months. In 24% of the patients, relapse did not develop until the second year after treatment had ceased. Following withdrawal of liver extract in another group of 12 patients, six failed to show hematologic relapse in 26 to 29 months, and in the remainder relapse developed in eight to 18 months.<sup>306</sup> Remission lasted 42 to 78 months in four patients. In none did neurologic manifestations appear. It is probable that the time of recurrence of relapse will not always be the same even in the same patient.

The most serious long-term complication of pernicious anemia is carcinoma of the stomach. The apparent frequency of this complication varies with the method of detection. At autopsy, 5.2% of 2115 patients with pernicious anemia were found to have gastric carcinoma.<sup>23</sup> Combined studies based on clinical follow-up of living patients reveal that 2.3% of 8747 patients acquired this tumor.<sup>23</sup> This incidence is considered to be about three times that found in the general population.

The association of pernicious anemia with other hematologic disorders has been infrequent enough to have been the subject of case reports. Thirty-eight cases of association of pernicious anemia with leukemia (acute myeloblastic 14, chronic myelocytic 15, chronic lymphocytic 8, erythremic myelosis 1) have been reported.<sup>301,303,309,310</sup> In a prospective five-year study of 1625 patients with pernicious anemia, leukemia was found in three; the expected incidence in the general population would have been 0.89.<sup>301</sup> This increased

incidence of leukemia is of borderline statistical significance ( $p = 0.06$ ). At least 39 cases of polycythemia vera associated with pernicious anemia have been reported.<sup>23</sup> There are isolated cases of the coincidental occurrence of pernicious anemia and sickle cell trait<sup>304</sup> and erythrocytic hypoplasia.<sup>305</sup>

## Pathology

The morbid anatomic characteristics of pernicious anemia are now rarely encountered in the autopsy room. In the typical subject in relapse, the pathologist noted the yellowish appearance of the skin, the lack of wasting, and the dilated and flabby heart, as well as fatty changes in the parenchymatous viscera, especially the liver, heart, and kidneys. Heavy deposits of iron were found in the liver, spleen, and kidneys. The red bone marrow was found to be strikingly deepened in color and the yellow marrow of the long bones was transformed into a deep-red gelatinous substance that was likened to currant jelly. In the spleen and liver, foci of extramedullary blood formation were regularly found.

These changes are absent in patients dying as a result of intercurrent disease during vitamin B<sub>12</sub>-induced remission. In such patients, however, as well as in those dying in relapse, morphologic abnormalities are found in the *gastrointestinal tract*.

The mucosa of the tongue usually is atrophied. The changes in the stomach<sup>323,331</sup> are striking in tissue fixed soon after death. Severe atrophy of the upper two thirds of the stomach is evident even to the naked eye, this area being reduced to the thinness of parchment. At the junction of the body with the pyloric mucosa, the transition to the normal thickness of the stomach wall is usually abrupt. Microscopically, in the mucosa of the fundus and body of the stomach, the only structures seen are the surface epithelium and a few scattered glands lined by mucus-producing cells. The specialized oxyntic and peptic cells are not seen. However, there is no fibrosis, cellular infiltration, or other evidence of past inflammation. The muscle coat

Fig 15-6. Gastric columnar cells A, Normal. B, untreated pernicious anemia (Magnification 750 $\times$ ) (Courtesy of Dr Cyrus E Rubin)

likewise shows atrophy. No evidence of a reduction in the number of argentaffin cells, at one time proposed as the source of intrinsic factor, is found.<sup>329,331</sup> Findings on gastric biopsy were discussed previously (page 606). No reorganization of the mucosa follows intensive therapy.<sup>111,331</sup>

Examination of cells obtained from the stomach by gastric lavage and abrasion has revealed groups of columnar cells that differ from normal ones chiefly in size.<sup>332</sup> These cells are approximately twice the normal size, their nuclear membrane may be creased or folded in appearance, and small aggregates of chromatin stand out on the relatively empty background of nucleus. The cytoplasm, as well as the nucleus, is enlarged and has a more vacuolated and granular appearance than is normal (Fig. 15-6).

The nuclei of cells from the buccal mucosa are enlarged<sup>321</sup> and those from the vagina show atypical changes suggestive of neoplasia.<sup>325,330</sup>

Changes in the *central nervous system* vary in extent. Myelin degeneration and loss of

nerve fibers in the dorsal and lateral tracts of the cord, and degenerative changes in the dorsal root ganglia are commonly found. Following liver therapy an increase in gliosis has been reported.<sup>324</sup> Degenerate changes are not infrequent in peripheral nerves<sup>223,326,327</sup> and degeneration of the celiac ganglia and of Auerbach's and Meissner's plexuses as well as lesions in the lateral horns of the spinal cord have been described.<sup>322</sup> Changes similar to those found in the spinal cord have been observed in the brain.<sup>328</sup> The rarity of optic atrophy has been mentioned. Changes in other cranial nerves have not been described.

## *Anemias Characterized by Deficient Hemoglobin Synthesis and Impaired Iron Metabolism*

Definition and Detection  
Etiology and Pathogenesis  
Laboratory Evaluation  
Diagnostic Approach

THE anemias to be discussed in this chapter and in Chapters 17 and 18 are grouped together because they share important pathogenetic features: quantitatively deficient hemoglobin synthesis in association with impaired iron utilization or actual iron deficiency. When such a defect is present, erythrocytes may be formed in normal numbers, but they contain less than the normal amount of hemoglobin. As a result, the anemia in these disorders is most accurately measured by the blood hemoglobin concentration, which is reduced to a greater extent than either the red cell count or the volume of packed red cells.

In contrast to other forms of anemia, the major morphologic alterations in this group of anemias, when they are fully developed, are hypochromia and microcytosis. However, these morphologic characteristics may not always be present, especially when the anemia is mild or of short duration. At first the anemia is normocytic and may then become

somewhat hypochromic. The anemia of chronic disorders almost never progresses beyond this. Even when there is iron deficiency, the anemia does not become hypochromic or microcytic until several months after iron stores have been depleted. The sideroblastic anemias often are characterized by two populations of cells, only one of which is hypochromic and microcytic.

### **Definition and Detection of Hypochromic, Microcytic Anemia**

*Microcytosis* refers to the presence in the blood of abnormally small cells. In the strictest sense, the term means that the *volume* of each such cell is reduced. Usually, but not always, other dimensions, such as diameter and thickness, are decreased in proportion to volume. Simply because of their small size, microcytes contain less than the normal amount of hemoglobin.

*Hypochromia* indicates the presence of erythrocytes in which the *concentration* of hemoglobin is reduced. Obviously, hypochromic cells may be of normal size and still contain reduced amounts of hemoglobin.

When the *average* cell contains less than

**Table 16-2. Pathogenetic Classification of the Anemias Characterized by Deficient Hemoglobin Synthesis**

- A Disorders of iron metabolism
  - 1 Iron deficiency anemia (Chapter 17)
  - 2 Anemia of chronic disorders (Chapter 18)
  - 3 Atransferrinemia
  - 4 The Shahidi Nathan Diamond syndrome
  - 5 Hereditary hypochromic anemia (sla) in mice
  - 6 Experimentally induced copper deficiency in swine (Chapter 4)
- B Disorders of globin synthesis
  - 1 The thalassemias (Chapter 26)
  - 2 Certain other abnormal hemoglobin diseases (Chapters 24 and 25)
- C Disorders of porphyrin and heme synthesis sideroblastic anemias (Chapter 18)
  - 1 Defective  $\delta$ -aminolevulinic acid (ALA) synthesis
    - a Vitamin B<sub>6</sub> deficiency
    - b Defective vitamin B<sub>6</sub> metabolism induced by drugs or toxins
    - c Defective ALA synthetase activity
  - 2 Deficiency of coproporphyrinogen oxidase
  - 3 Deficiency of heme synthetase
  - 4 Lead intoxication
  - 5 Of unknown cause

*transferrinemia*, plasma iron is low. Its specific transport protein is lacking; disease is extraordinarily rare, having been reported only three times.<sup>36,32a,37</sup> The disease appeared to have been inherited as an autosomal recessive trait, since trans-ferrin values in the subjects' parents were half normal.<sup>32a,37</sup> The patients suffered from severe, refractory, hypochromic, microcytic anemia from infancy. Iron absorption was impaired. Excessive amounts of iron were present in the hepatic reticuloendothelium, but little iron was found in the bone marrow. Values for serum iron and TIBC were low and ferrokinetic studies demonstrated that the ability of marrow normoblasts to utilize iron for hemoglobin synthesis was severely impaired. These abnormalities were corrected by the administration of iron.<sup>32a</sup> One child died of cardiac failure secondary to hemosiderosis.<sup>37</sup> Extremely rare is the disorder that Shahidi, Nathan, and Diamond described in two siblings, one male and one female.<sup>61</sup> In these children, the anemia was severely hypochromic and microcytic. The serum iron level was low and the transferrin was completely

saturated. Hepatic parenchymal cells contained grossly excessive amounts of iron, but none was found in hepatic or bone marrow RE cells. Similar findings were reported in another pair of siblings.<sup>62a</sup> The nature of the defect in these families remains unknown. Shahidi, Nathan, and Diamond suggested that there was an abnormality in RE function and that developing normoblasts became deficient in iron because they received none by direct transfer (ropheocytosis) from marrow RE cells. However, although such a transfer may indeed occur (Chapter 4), amounts of iron adequate for normal hemoglobin synthesis can be supplied by transferrin alone.<sup>42</sup> It is tempting to surmise that in these children there was a functional defect in the transfer of iron from transferrin to immature erythrocytes. However, such a defect was searched for and could not be found.

An X-linked gene (sla) gives rise to hereditary hypochromic anemia in mice.<sup>2</sup> These animals absorb iron poorly, as has been demonstrated in vivo as well as in studies with everted duodenal sacs.<sup>2,52</sup> However, defective iron absorption cannot fully explain the anemia, since affected mice become anemic in

ro despite normal placental iron transfer.<sup>20</sup> Furthermore, although the hemoglobin rises when iron is given parenterally, the response is not complete. Thus, additional defects in iron utilization probably exist in this animal model.

The hypochromic, microcytic anemia of copper-deficient swine has been discussed in chapter 4 (page 150).

### Disorders of Globin Synthesis

The thalassemias are a group of inherited disorders in which synthesis of one of the normal polypeptide chains of globin is severely deficient (Chapter 26). In the heterozygous state (thalassemia minor), hypochromia and microcytosis may be prominent, even though anemia is usually absent or mild. In more severe thalassemic disorders, including beta-thalassemia major and hemoglobin H disease, hypochromic, microcytic anemia may be severe.

In thalassemia, the cellular hemoglobin deficit comes about by two mechanisms. The first of these is the aforementioned defect in synthesis of one of the normal chains, for example, the beta chain in beta thalassemia. The second mechanism is related to the fate of the complementary normal chain. In beta thalassemia, excess alpha chains are formed. These, being poorly soluble, precipitate intracellularly forming inclusions resembling Heinz bodies.<sup>26</sup> The inclusions evidently can be removed by the normal spleen without the cell being destroyed. The result is a cell even more deficient in hemoglobin than would be predicted by the magnitude of the synthetic defect.

In most of the abnormal hemoglobin diseases, the hemoglobin is *qualitatively* abnormal, but synthesis is not impaired. In a few diseases, however, the anemia may be moderately microcytic. These include hemoglobin C disease<sup>62</sup> and hemoglobin E disease.<sup>14</sup> Pronounced hypochromia may sometimes be detected in unstable hemoglobin disease (Chapter 24) because heme may be lost when the abnormal hemoglobin precipitates intra-

cellularly and also because of Heinz-body removal.

### Sideroblastic Anemias

These are disorders which have in common the presence of ringed sideroblasts in the bone marrow,<sup>53</sup> a morphologic finding that indicates accumulation of iron in mitochondria.<sup>4</sup> The classification of all sideroblastic anemias as disorders of porphyrin and heme biosynthesis (Table 16-2) must be considered tentative since the pathogenesis is unknown in many instances.

A number of the sideroblastic anemias (pp. 678-689) result from defective synthesis of delta-aminolevulinic acid, the first step in porphyrin synthesis. This reaction requires the coenzyme form of vitamin B<sub>6</sub>, pyridoxal phosphate. Therefore, induced vitamin B<sub>6</sub> deficiency in animals leads to sideroblastic anemia.<sup>22,45</sup> Vitamin B<sub>6</sub> deficiency is rare in man, but lack of coenzyme B<sub>6</sub> can come about by other means. For example, ethanol<sup>39</sup> and certain antituberculosis drugs (isoniazid,<sup>50,66</sup> cycloserine,<sup>66</sup> pyrazinamide<sup>49</sup>) occasionally produce sideroblastic anemia by interfering with formation of pyridoxal phosphate from its precursors.<sup>39,48,60</sup> Again, some hereditary and acquired sideroblastic anemias respond to pharmacologic doses of vitamin B<sub>6</sub> and are therefore called pyridoxine-responsive anemias.<sup>35</sup> The exact nature of the defects in this heterogeneous group is not known, but at least some of them may represent abnormalities of the enzyme, aminolevulinic acid synthetase.<sup>45,67</sup>

There are other examples of sideroblastic anemia in which defective heme synthesis seems well established. A rare, hereditary anemia has been observed in which coproporphyrin oxidase appears to be defective.<sup>30,36</sup> A patient with heme synthetase deficiency has been reported.<sup>59</sup> Intoxication with lead inhibits several of the heme biosynthetic enzymes.<sup>32</sup> On the other hand, a defect in heme synthesis has not been documented in the relatively common acquired, idiopathic or secondary forms of sider-

oblastic anemia that do not respond to pyridoxine.<sup>40,41</sup>

## Laboratory Tests Useful in Detection and Differential Diagnosis

### Hematologic Observations

There usually is little difficulty in distinguishing typical, well-developed iron-deficiency anemia from the anemia of chronic disorders. Anemia, hypochromia, and microcytosis generally are much more pronounced in iron deficiency (Table 16-3) than in the chronic disorders, as are the degrees of anisocytosis and poikilocytosis. However, when the iron deficiency is early and mild, morphologic findings in the two diseases may be similar.

Thalassemia minor can usually be identified by finding an MCV that is unusually low for the mild degree of anemia (Table 16-3) and by the presence of apparent hypochromia (see above). A discriminatory function (DF)

has been developed that can distinguish iron deficiency from thalassemia trait with erythrocyte indices alone.<sup>25a</sup> It is calculated from the formula:

$$DF = MCV - RBC - (5 \times Hb) - 34$$

Positive values for DF indicate iron deficiency; negative values, thalassemia trait. In addition, basophilic stippling and target cells are more prominent in thalassemia than in iron deficiency. However, detection of these changes may require very careful scrutiny of the blood smear, since the changes may not be striking. There is rarely any problem in detecting thalassemia major, because the severe hypochromic, microcytic anemia is accompanied by signs of hemolysis, including reticulocytosis and increased plasma bilirubin. Furthermore, the blood smear is characterized by the presence of normoblasts, and marked anisocytosis and poikilocytosis, as well as by stippling and target cells.

Homozygous hemoglobinopathies are usually microcytic and normochromic, and there are many target cells in the blood smear.<sup>14,62</sup>

The various forms of sideroblastic anemia

**Table 16-3. Degree of Anemia, Microcytosis, and Hypochromia in Certain Anemias**

	Hb g/dl	MCV fl	MCHC g/dl
Normal	♂ 16 (14-18) ♀ 14 (12-16)	89 (83-96)	34 (32-36)
Iron-deficiency anemia <sup>1</sup>	7.5 (4-12)	74 (53-93)	28 (22-31)
Anemia of chronic disorders <sup>19</sup>	10.4 (8-13)	86 (70-95)	32 (26-36)
Thalassemia (Chapter 26)			
Minor	11.6 (9-14)	68 (56-75)	31 (29-33)
Major	(2-7)	(48-72)	(23-32)
Hemoglobin H <sup>41b</sup>	8.8 (7-11)	70 (53-88)	25 (24-28)
Abnormal hemoglobins			
CC <sup>42</sup>	10.4 (7-14)	74 (55-93)	32 (23-38)
EE <sup>14</sup>	10.5 (8-13)	69 (66-72)	32 (29-34)
Sideroblastic anemia			
Hereditary <sup>15</sup>	6.4 (4-10)	77 (49-104)	25 (14-30)
IRSA <sup>44</sup>	10.0 (7-12)	104 (83-118)	32 (26-36)

Values are means with approximate range in parentheses. Abbreviations: Hb, blood hemoglobin concentration; MCV, mean corpuscular volume; MCHC, mean corpuscular hemoglobin concentration; IRSA, idiopathic refractory sideroblastic anemia.

Table 16-4. The Blood Smear in Hypochromic, Microcytic Anemia

	Anisocytosis, Poikilocytosis	Basophilic Stippling	Target Cells	Dimorphism
Iron-deficiency anemia	1-3+	0	±	±
Anemia of chronic disorders	±	0	±	±
Thalassemia				
Minor	1+	2+	5%(0-37%)*	0
Major	3+	3+	3+	0
Hemoglobin C or E disease	2+	±	50%(10-90%)*	0
Sideroblastic anemia				
Hereditary	3+	2+	2+	3+
IRSA	1+	2+	±	3+

\*Expected % of target cells in smear

Abbreviations, 0, none, ±, may be present, 1+, present, 2+, easy to find 3+ prominent, IRSA, idiopathic refractory sideroblastic anemia

differ considerably in their hematologic manifestations. However, the two most typical features are erythrocyte dimorphism—a hypochromic population of cells mixed with a relatively normal population on smear—and the presence of occasional, heavily stippled, hypochromic cells. In hereditary (X-linked) sideroblastic anemia, the anemia, hypochromia, and microcytosis are pronounced (Table 16-3), and these changes are accompanied by considerable anisocytosis and poikilocytosis, with numerous target cells. In acquired, idiopathic, refractory sideroblastic anemia (IRSA), the hypochromic population is small; the MCV is usually increased and the MCHC is normal or slightly decreased.

## Iron Metabolism

### Serum Iron and Iron-Binding Capacity

The study of iron metabolism should begin with a determination of serum iron and total iron-binding capacity. The determinations are relatively simple, but certain precautions must be taken in collecting the specimen. The patient should have fasted for 12 hours and should not have consumed any iron-containing medication for at least 24, and preferably 72 hours. Specimens should be obtained in the morning because the normal diurnal variation results in low values later in the day.<sup>5</sup>

Syringes, needles, and sample containers must be free of iron; ordinary laboratory glassware is usually contaminated with iron unless specially processed, but most plastic ware is iron-free. Standard methods for preparing glassware and determining plasma iron colorimetrically have been recommended by an international committee.<sup>41</sup> Several methods are available for measuring TIBC,<sup>7,69,71</sup> which is an indirect measure of serum transferrin content.

From the serum iron and TIBC, transferrin saturation can be calculated by the following formula:

Transferrin saturation (%)

$$= \frac{\text{serum iron } (\mu\text{g/dl}) \times 100}{\text{TIBC } (\mu\text{g/dl})}$$

The normal value for transferrin saturation is 20 to 45%.

In both iron deficiency anemia and the anemia of chronic disorders, the value is reduced below 16% (Fig. 16-2).<sup>1</sup> The degree of reduction tends to be greater in iron deficiency than in chronic disorders, but there is considerable overlap between these two conditions. A value of less than 5% is almost certainly due to iron-deficiency anemia. In sideroblastic anemias, transferrin saturation is almost invariably increased and often approaches 100%.

The absolute value for TIBC may be help-

Fig 16-2. Transferrin iron saturation in patients with several types of anemia. The values are low (less than 16%) in both iron deficiency and the anemia of chronic disorders, with considerable overlap. Values of less than 5% are found only in iron deficiency. Transferrin saturation is increased in sideroblastic anemia.

ful in distinguishing between iron deficiency and the anemia of chronic disorders. Often, TIBC is increased in iron deficiency and decreased in chronic disease (Fig. 16-3). However, there is considerable overlap between values in the two groups. In iron deficiency a bimodal distribution of values for TIBC has been observed and, in a proportion of patients, the TIBC may be decreased (Fig. 16-3). When these patients are studied further, they are found to have a generalized hypoproteinemia, one indication of which is decreased serum albumin concentration.<sup>1</sup>

### Measurement of Iron Stores

In order to measure iron stores, it usually is necessary to sample one of the two principal storage depots, the bone marrow or the liver. Aspiration and biopsy<sup>46</sup> of marrow usually are preferred because they are probably safer and also the technique is more familiar to hematologists than liver biopsy.

If bone marrow aspirates are used, it is essential to be certain that there is an adequate number of marrow particles in the smear. Some prefer to assess thick smears that are unstained.<sup>54</sup> In such preparations, hemosiderin appears as golden-yellow, refractile granules. More often, the specimen is stained by the Prussian blue method,<sup>55</sup> which colors hemosiderin blue. With experi-

ence, the marrow hemosiderin stores can be graded from 0 to 6+ (Table 16-5 and Plate X).<sup>29</sup> Good correlation between histologic grading and iron content has been found.<sup>29,61</sup> Normal marrow is graded 1+ to 3+. In iron deficiency, marrow hemosiderin is absent; in

### TOTAL IRON-BINDING CAPACITY (TIBC) IN IRON DEFICIENCY

Fig 16-3. Total iron-binding capacity (TIBC) in patients with iron deficiency and in those with chronic disease. A high value indicates iron deficiency. Low values are found in chronic disease, but may also occur in iron deficiency.

Iron stores in bone marrow ( $\times 100$ ). Also sideroblasts and siderocytes ( $\times 1000$ ). A-F, Bone marrow biopsies (A, C, E) and crush (aspiration) preparations (B, D, F), stained with Prussian blue for iron, showing normal bone marrow iron (A, B), absence of iron (C, D) and excessive iron stores (E, F). A, C, E counterstained with Giemsa. Sideroblasts are shown in G and H, the latter being 'ringed'. I and J are siderocytes.

Table 16-5. Criteria for Grading Iron Stains in Bone Marrow Aspirates<sup>29</sup>

Grade	Criteria	Iron Content ( $\mu\text{g/g}$ ) <sup>*</sup>
0	No iron granules observed	$43 \pm 23$
1+	Small granules in reticulum cells, seen only with oil immersion lens	$130 \pm 50$
2+	Few small granules visible with low-power lens	$223 \pm 75$
3+	Numerous small granules in all marrow particles	$406 \pm 131$
4+	Large granules in small clumps	$762 \pm 247$
5+	Dense large clumps of granules	$1618 \pm 464$
6+	Very large deposits obscuring marrow detail	$3681 \pm 1400$

<sup>\*</sup>M  $\pm$  SD

the anemia of chronic disorders, iron is always present, most often with a grade of 2 or 3+ but sometimes 4 or 5+.<sup>1</sup> In cases difficult to diagnosis, study of marrow hemosiderin is the most reliable way of distinguishing between iron deficiency and the anemia of chronic disorders. Iron stores are normal or moderately increased (2 to 4+) in thalassemia minor and in the homozygous hemoglobinopathies. They are greatly increased (5 to 6+) in thalassemia major and in sideroblastic anemias.

Iron stores can also be estimated by liver biopsy. Both histochemical<sup>51</sup> and chemical<sup>28</sup> methods of analysis have been described. Conventional needle biopsy techniques with Menghini or Vim-Silverman needles or a fine needle aspiration method<sup>47</sup> have been used. The latter procedure is said to be free of complications. Criteria for grading the preparations from 0 to 4+ have been published,<sup>28,47,51</sup> and these correlate well with chemical analysis.<sup>28</sup>

Storage iron also has been evaluated by urinary excretion of iron after the administration of a chelating agent.<sup>16,23,27,34,55</sup> The chelator most commonly employed for the purpose is deferoxamine (DFOM); diethylenetriaminopentaacetic acid (DTPA) is less satisfactory.<sup>34</sup> In the DFOM test, 500 mg of DFOM are given (im) and iron is measured in urine collected during the subsequent 24

hours. The more complicated differential ferroxamine test requires the injection of <sup>59</sup>Fe-labeled ferroxamine to correct for the fraction of chelate that is not excreted into the urine.<sup>27</sup> Little is gained by this added complexity.<sup>34</sup>

There is a rough correlation between iron stores and urinary iron excretion after DFOM. In one study, excretion in normal subjects averaged 0.7 mg, range 0.1 to 3.6; in iron deficient subjects, excretion was 0.1 mg, range 0 to 1.7; and in sideroblastic anemia, 7.8 to 15.5 mg.<sup>34</sup> As these data imply, the test is useful in detecting iron overload. It is less reliable in detecting deficient stores because the values found in normal and in iron-deficient subjects overlap.<sup>34,55</sup> The chelatable iron probably is a measure of parenchymal cell iron rather than total stores,<sup>34</sup> although a contrary view has been expressed.<sup>16</sup>

A novel in vivo method of estimating iron stores, based on the magnetic susceptibility of ferritin and hemosiderin, has been described.<sup>3</sup> A large, semicircular transformer was constructed which included an air gap between the primary and secondary windings. The magnetic properties of specimens placed in this gap affected electron flow in the secondary winding. When the body of a rat was moved slowly through the gap and scanned for magnetic susceptibility, values obtained correlated well with chemical liver analysis.

As yet, apparatus suitable for human use has not been constructed.

According to one study,<sup>41a</sup> the status of iron stores can be estimated by measuring the ferritin in serum. With a radioimmunologic assay, the mean serum ferritin concentration was 69  $\mu\text{g/l}$  in men and 35  $\mu\text{g/l}$  in women. The range was wide in both sexes, but levels below 10  $\mu\text{g/l}$  were associated with iron deficiency. Values greater than 1000  $\mu\text{g/l}$  were common in iron overload states, including sideroblastic anemia.

### *The Cobalt Excretion Test*<sup>65</sup>

The gastrointestinal absorption of cobalt correlates closely with the absorption of iron. Unlike iron, however, much of the absorbed cobalt is excreted into the urine. These properties of cobalt form the basis for the cobalt excretion test, which may be considered to be an indirect measure of iron absorption. In this test, cobalt (20  $\mu\text{moles}$  and 0.5  $\mu\text{Ci}$  in 100 ml 0.01 N HCl) is given by mouth, and the urinary excretion of the isotope is measured. Normal subjects over 30 years of age excreted an average of 7.3% (range, 4 to 11%) into the urine in a six-hour period.<sup>65</sup> In younger subjects, age 15 to 30, slightly higher values were found, mean 10% (range 5 to 14%). In iron deficiency, cobalt excretion was increased to a mean of 18% (range 12 to 26%) in patients over 30 years of age and to 19% (range 15 to 27%) in patients 15 to 30 years of age. Thus, the test clearly distinguishes iron-deficient subjects from normal persons. Since the results become abnormal as soon as iron stores are depleted, the test may provide one of the earliest and most sensitive laboratory means for detecting iron deficiency. Values for the cobalt excretion test fell within normal limits in 30 patients with a miscellaneous group of anemias not due to iron deficiency, including several patients with the anemia of chronic disorders and one with thalassemia minor. However, cobalt excretion is increased in idiopathic hemochromatosis, and also in other situations in which iron absorption may be increased in the absence of iron deficiency, such as acute

blood loss and hemolytic anemia. Since iron absorption may be increased in thalassemia major and in sideroblastic anemia, it is likely that cobalt excretion will be increased in these conditions as well.

### *Sideroblasts and Siderocytes*

Nucleated red cells that contain stainable iron granules are known as sideroblasts. These cells can be observed and counted in marrow aspirations stained with the Prussian blue technique and counterstained with saffranin.<sup>10</sup> In the experience of some investigators, the staining procedure must be carried out at 56° C when sideroblasts are to be counted,<sup>1,24</sup> although others have not found this to be necessary.<sup>10</sup>

Usually, the number of cells containing iron granules is recorded as percent of all the normoblasts present. It is useful to note the number and size of the granules, since more than five small granules in each normoblast are considered abnormal.<sup>24</sup> It also is most important to note the presence of so-called ringed sideroblasts.<sup>6</sup> These are normoblasts in which five or more granules form a partial or complete ring about the nucleus (Plate X). It is rare to find even one such cell in normal marrow.

In normal subjects, 30 to 50% of the red cell precursors are sideroblasts. Both in normal subjects and in patients with a variety of anemias, there is excellent correlation between transferrin saturation and the proportion of sideroblasts<sup>1</sup> (Fig. 16-4). However, a great deal of experience in counting sideroblasts is required to reproduce this correlation. Marrow sideroblasts are decreased to less than 10% (average 2.5%) in iron deficiency. They are also decreased, but to a lesser degree (6 to 20%, mean 13%), in the anemia of chronic disorders. In these situations, marrow sideroblasts offer no more information than does the value for transferrin saturation.

The most important application of sideroblast counts is in making the diagnosis of sideroblastic anemia. This group of anemias is characterized by excessive accumulation of iron within the mitochondria of normo-

Fig 16-4 Relation between marrow sideroblast count and transferrin saturation (From Bainton and Finch,<sup>1</sup> courtesy of the authors and American Journal of Medicine)

blasts.<sup>4</sup> Mitochondria characteristically are distributed about the nucleus and the presence of iron granules in a similar distribution suggests that the iron is in the mitochondria. Admittedly, electron microscopy is required to determine the presence of mitochondrial iron deposition with certainty, but for clinical purposes the detection of ringed sideroblasts is adequate evidence of this. In sideroblastic anemia, most of the normoblasts are sideroblasts, but, more specifically, many of them are ringed.<sup>53</sup>

The enumeration of *siderocytes* (circulating erythrocytes containing iron granules) yields less valuable information, probably because the spleen removes siderotic granules shortly after the red cells have entered the circulation. Of 11 patients with sideroblastic anemia, only six had increased numbers of circulating siderocytes.<sup>43</sup> The number of siderocytes was also increased in patients with severe hemolytic anemia and in those who had been splenectomized or had splenic atrophy.

#### Free Erythrocyte Protoporphyrin

Under normal circumstances, red cell precursors synthesize slightly more proto-

porphyrin than is needed for heme synthesis. The excess remains with the cell and is called free erythrocyte protoporphyrin (FEP). The normal concentration varies somewhat with the method and the laboratory, but composite normal limits are approximately from 15 to 80  $\mu\text{g/dl}$  red cells.<sup>70</sup> Although known to be a sensitive indicator of disorders of heme synthesis, the FEP has been used only rarely for clinical purposes because methods for its determination have been exceedingly tedious and time-consuming.<sup>70</sup> A new, simplified method that makes possible the analysis of one specimen in 30 minutes or 12 in 2 hours has been described.<sup>38</sup> Such a method should bring the determination within the reach of the routine clinical laboratory.

FEP increases approximately fivefold in iron-deficiency anemia.<sup>13,19,36</sup> Furthermore, it is one of the earliest and most sensitive biochemical abnormalities associated with this disorder.<sup>41a</sup> It was found to be elevated in 13 of 15 patients with latent iron deficiency (ie, deficient stores but no anemia).<sup>19</sup> FEP increases in the anemia of chronic disorders to a degree similar to that found in iron-deficiency anemia.<sup>9,41a</sup> The increase appears to be better related to the duration than to the severity of the anemia.

FEP was found to be increased in thalassemia in one study,<sup>36</sup> but not in others.<sup>31,58,63</sup>

Changes in FEP in sideroblastic anemia vary with the nature of the lesion. In vitamin B<sub>6</sub>-deficient swine, FEP was reduced and the value returned to normal after administration of pyridoxine.<sup>12</sup> A similar response has been observed in pyridoxine-responsive anemia in man.<sup>57,67</sup> One variety of hereditary sideroblastic anemia is characterized by very low values for FEP combined with high values for erythrocyte coproporphyrin, and is thought to represent a defect in the coproporphyrinogen oxidase reaction.<sup>30,36</sup> In contrast, FEP is usually increased in idiopathic refractory sideroblastic anemia, and becomes further increased with pyridoxine therapy.<sup>44</sup> In one patient, whose illness was thought to represent a defect in the heme synthetase reaction, FEP was elevated to extremely high levels,

1750 µg/dl, and this was associated with dermal photosensitivity.<sup>59</sup>

In lead poisoning, FEP is increased and other abnormalities in porphyrin metabolism also are observed. These include excessive excretion of delta-aminolevulinic acid and coproporphyrin into the urine.<sup>32</sup>

### Globin

Methods used in evaluating the protein portion of the hemoglobin molecule are discussed in detail in Chapter 24. Beta-thalassemia minor may be detected by an increase in the proportion of hemoglobins A<sub>2</sub><sup>31</sup> or F.<sup>15</sup> In contrast, the value for hemoglobin A<sub>2</sub> decreases in iron deficiency.<sup>68</sup> In beta-thalassemia major, hemoglobin F usually is greatly increased.

Alpha-thalassemia minor may be detected

## THE HYPOCHROMIC, MICROCYTIC ANEMIAS

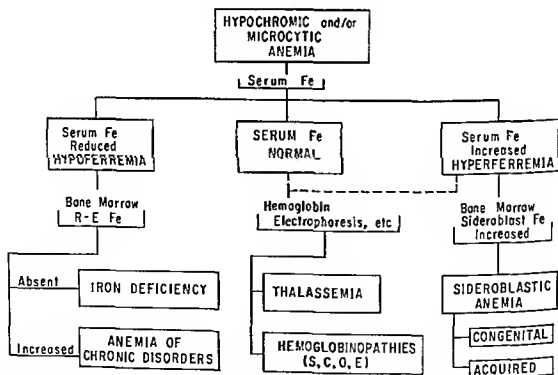

Fig. 16-5 Flow sheet for diagnosis of hypochromic, microcytic anemia. The dashed line is meant to indicate that hyperferremia may be found in thalassemia.

by the presence of hemoglobin Barts ( $\gamma_4$ ) at birth or of hemoglobin H inclusion bodies in older individuals,<sup>41b</sup> but the hemoglobin often is completely normal in older children and adults. Hemoglobins C, E, and H may be detected by electrophoresis; unstable hemoglobins, by the heat-denaturation test (Chapter 24).

## Diagnostic Approach

A tentative diagnosis usually is possible after the initial history has been obtained and the physical examination and hematologic evaluation have been completed. History-taking should be directed toward ascertaining whether the condition is congenital, as it is in thalassemia and other hemoglobinopathies and in hereditary sideroblastic anemias, or acquired, as it is in iron deficiency, the anemia of chronic disorders, and acquired sideroblastic anemia. A careful evaluation for blood loss and other etiologic factors in iron deficiency should be made (Chapter 17). Possible diseases associated with the anemia of chronic disorders, such as rheumatoid arthritis, infection, and carcinoma, should be searched for. This information, together with the hematologic data discussed previously, often is adequate to establish the diagnosis.

When the diagnosis remains obscure, or when confirmation of the clinical impression is needed, the steps indicated in Figure 16-5 should be followed. An accurate determination of serum iron permits classification into one of three categories (Figs. 16-2 and 16-5). When the serum iron is reduced (transferrin saturation less than 16%), only iron deficiency and the anemia of chronic disorders need be considered and these can be distinguished by estimation of iron stores as judged by bone marrow examination, or, possibly, by performing the cobalt excretion test. High transferrin saturation suggests sideroblastic anemia, and its presence can be confirmed by examination of the bone marrow after staining for iron. The amount of iron in the serum in patients with thalassemia or the hemoglobinopathies usually is normal

but may be increased. Diagnosis is based on family studies and analysis of the hemoglobin (see Chapters 24 and 26.)

### History

The therapeutic use of iron was mentioned in Greek mythology in the story of Iphylus, who was cured of impotence by drinking iron rust dissolved in wine. Much of the iron therapy used by ancient physicians had its origin in such sympathetic magic, the sufferer hoping to assume something of the strength of steel by drinking water or wine in which a sword had rusted. The specific use of iron salts is credited to Sydenham who, in the early 1700's, recommended iron for treatment of chlorosis.

*Chlorosis*, a term derived from the Greek

word meaning green, was applied by Varandaeus<sup>21</sup> to a disorder which was first described in 1554 by Johannes Lange who called it "De morbo virgineo."<sup>20</sup> The disease became well known, not only in medical circles, but also to the laity, who called it the "green-sickness." It was depicted in many paintings by the Dutch masters and was alluded to by Shakespeare, Izaak Walton, and other literary figures of the period.<sup>15</sup> Chlorosis occurred almost exclusively in adolescent girls between the ages of 14 and 17. The most prominent manifestation was the greenish pallor which perhaps required "the eye of faith" to discern.<sup>6</sup> Other clinical features were breathlessness, palpitations, slight ankle edema, and gastrointestinal complaints, including perversion of the appetite, flatulence, abdominal pain, and constipation. Emotional disturbances ("love sickness"), depression, irritability, and moodiness were usual. Thrombophlebitis was a relatively common complication, and there was a particularly striking incidence of cerebral sinus thromboses.

It is clear that iron-deficiency anemia was a prominent part of the picture of chlorosis. In the 1830's, anemia, hypochromia, and lack of iron in the blood were detected by Hoefer, Popp, and Foedisch, respectively,<sup>15</sup> and Ashwell was able to classify chlorosis as a disease of the blood.<sup>1</sup> In 1832, Pierre Blaud described the response of chlorosis to his de-

servedly famous pills (ferrous sulfate plus potassium carbonate). He gave gradually increasing doses, from 2 pills on the first day to 12 on the sixteenth day. Many excellent observers, including Niemeyer and Osler, confirmed his findings.<sup>16</sup>

As knowledge of iron metabolism has grown, most present-day investigators have come to view chlorosis as resulting from a combination of factors affecting adolescent girls: the demands of growth and the onset of menses, an inadequate diet, and a legacy of poor iron stores at birth from an iron-deficient mother. Others have pointed out that it is difficult to reconcile this concept with observations on the fluctuations in the incidence of the disease.<sup>23</sup> Chlorosis became especially common in the last decade of the 19th century. It then abruptly declined in incidence until only rare cases were observed after 1910. It is perhaps true that the disappearance of chlorosis has been exaggerated, since even today iron deficiency of moderate degree is by no means uncommon in girls and young women. Nevertheless, clinicians whose observations spanned the decades between 1890 and 1920 were astounded at the abrupt disappearance of a disease that had filled the benches of their waiting rooms and a large proportion of their hospital beds.<sup>24</sup> The most prominent hypothesis offered to explain the changing incidence of chlorosis relates the disease to tight lacing of the body with a corset or similar garment, a hypothesis that continues to attract advocates.<sup>21,23</sup> The case for this cause of chlorosis rests chiefly on the relation between the use of the corset and the incidence of the disease throughout the previous centuries.<sup>17</sup> Lacing as an adjunct to female fashion appears to have been introduced in the 16th century near the time of Lange's initial description of chlorosis. The corset was abandoned by most women, especially young women, near the turn of the century when the incidence of chlorosis markedly decreased. Furthermore, a decrease in the incidence of chlorosis probably accompanied the temporary disuse of the corset in the period from 1790 to about 1820. Although these time relations are impressive,

the theory has not been generally accepted because of failure to demonstrate a clear pathogenetic relation between lacing of the body and the development of iron deficiency. Extreme degrees of lacing compress the liver and lead to considerable displacement of abdominal organs (visceroptosis); however, there is no known way in which such changes lead to either defective absorption or excessive loss of iron.

A second form of iron deficiency which attracted considerable attention in the first three decades of the 20th century initially was called "idiopathic" or "primary" hypochromic anemia but was later termed "chronic hypochromic" anemia as its pathogenesis was clarified. This disorder differs in no important respect from iron-deficiency anemia as we know it today. Like chlorosis, chronic hypochromic anemia was found to be a disease chiefly affecting women; it differed from chlorosis in that it was detected later in life, especially in the fourth and fifth decades.<sup>27</sup> Other distinguishing clinical features were widespread epithelial changes involving the tongue and nails, as well as achlorhydria, which Witts believed to be of specific differential diagnostic value.<sup>28</sup> The anemia was most common among women with poor diets, multiple pregnancies, and menstrual irregularities. Although it is clear in retrospect that chronic hypochromic anemia responded to iron, at one time there was considerable disagreement on this point. In the period 1890 to 1920, iron therapy became discredited chiefly because of Bunge's claim that inorganic iron is valueless and that only organic preparations should be used, but also because von Noorden taught that no more than 0.1 g of metallic iron is necessary.<sup>16</sup> Furthermore, physicians failed to distinguish between iron-deficiency anemias and anemias due to other causes.

## Iron-Deficiency States

*Iron deficiency* is used to designate a condition in which the total body iron content has been depleted, no matter what the cause. The designation should not be taken to mean that

iron depletion has necessarily come about through nutritional deficiency. To avoid any such implication, the alternative term *iron-lack* has been proposed<sup>18</sup> but has not found general acceptance.

Since body stores of iron must be exhausted before red cell production is restricted, anemia is a late stage of iron deficiency. In the mildest stage, *prelatent iron deficiency*, the reticuloendothelial iron stores are subnormal but there is no biochemical evidence of deficiency.<sup>5,7,19</sup> The only physiologic consequence of prelatent deficiency is a compensatory increase in the rate of iron absorption,<sup>4,19</sup> an alteration which may be detected by means of the cobalt excretion test (Chapter 16, page 630).

*Latent iron deficiency* may be said to exist when iron stores are exhausted, but the blood hemoglobin level remains above the lower limit of normal.<sup>5,7,9,12,14,22,25,26</sup> In this stage, certain biochemical abnormalities in iron metabolism are usually detected, such as an increase in free erythrocyte protoporphyrin and a reduced plasma iron level.<sup>9</sup> There may also be less than normal urinary iron excretion following an injection of desferrioxamine B,<sup>14,21</sup> a decrease in tissue cytochrome oxidase levels,<sup>9</sup> and, much less regularly, a reduced value for the MCHC.<sup>22</sup> One study suggested that latent iron deficiency is

symptomatic,<sup>3</sup> but others have not.<sup>9,10,13</sup>

*Iron-deficient erythropoiesis* refers to any situation in which red cell production is limited by the plasma iron level.<sup>2</sup> Such a limitation regularly occurs when transferrin saturation falls below 16%.<sup>2</sup> Iron-deficient erythropoiesis does not always indicate iron deficiency since it also accompanies the reticuloendothelial iron block found in the anemia of chronic disorders (Chapter 18). As a consequence of iron-deficient erythropoiesis, the blood hemoglobin level falls, and newly formed red cells contain reduced amounts of hemoglobin.

An experiment in which normal volunteers were depleted of iron by phlebotomy demonstrated that, early in the course, most of the circulating red cells were normal, and erythrocyte indices were therefore not altered; however, a few abnormal cells were found in blood smear.<sup>8</sup> In time, microcytosis became apparent, and both the MCV and the MCHC were reduced. At this stage, the total iron-binding capacity increased. Still later in the course, the MCHC fell below normal.<sup>8</sup> Tissue iron levels probably do not become reduced to a level at which abnormalities of epithelium are observed until the deficiency is of very long duration. This progression forms the basis for the stages of iron deficiency outlined in Table 17-1.

## Prevalence

Iron deficiency probably is the most common form of nutritional deficiency, in both developing and developed countries.<sup>46</sup> It is reported to be the most common cause of anemia, both in general medical practice<sup>35</sup> and in the practice of clinical hematology<sup>32,41</sup> and is even alleged to be the most common organic disorder seen in clinical medicine.<sup>34</sup>

Despite these assertions, there are relatively few adequate studies of the prevalence of iron deficiency in various populations. The most commonly employed screening procedure has been a simple blood hemoglobin determination. As measured by this test, anemia was defined by the World Health Organization (WHO) as a value below 14 g/dl in men, 12 g/dl in nonpregnant women, and 11 g/dl in pregnant women.<sup>46</sup> Such a screening method cannot, by definition, detect *latent* iron deficiency. Furthermore, inaccuracies are introduced by anemias due to causes other than iron deficiency. Finally, hemoglobin values in "anemic" and "normal" populations overlap; a more sophisticated statistical analysis of the distribution curve is required in order to determine true prevalence.<sup>31</sup> Screening by determination of plasma iron and iron-binding capacity obviates some of these inaccuracies, but the procedure is more cumbersome and consequently has been performed less frequently. Still less suited for the study of large groups is determination of reticuloendothelial iron stores by bone marrow aspiration.<sup>45</sup> The response of a test population to iron medication is a widely applicable procedure.<sup>37</sup> Probably the most important source of error in population surveys is the selection of samples. Most reported series are heavily weighted with representatives of low economic groups, a bias which may increase apparent prevalence.

A representative group of population studies appears in Table 17-2. In most developed countries, about 3% of adult men, 20% of adult women, and over 50% of pregnant women are deficient in iron, as judged by plasma iron levels. Still higher figures are

found in countries such as India where malnutrition is widespread. The prevalence of iron deficiency in the United States has not been well studied.<sup>7</sup> Available data are based only on blood hemoglobin values (Table 17-2), and the criteria for abnormal levels have not always been those accepted by WHO and used in other studies. Furthermore, there has been little selection of samples to delineate social, economic, and geographic influences.

A still greater prevalence of iron deficiency would presumably be detected if iron stores were evaluated. A study of 114 healthy, white, nulliparous, socioeconomically privileged girls demonstrated that 24% of them had no storage iron and that an additional 42% had suboptimal stores.<sup>45</sup>

Iron deficiency is also common among children, especially during the first two years of life. Hypoferremia (transferrin saturation less than 15%) was found in about 30% of a carefully selected sample of 3423 preschool children from multiple geographic locations in the United States.<sup>43</sup> The incidence of hypoferremia was greatest (47%) in children 12 to 24 months of age, decreasing to 21% in five- to six-year olds. In the 12- to 24-month age group, hypoferremia was most common (62%) in children from lower socioeconomic groups, but prevalence was remarkably high (39%) even in children of upper middle class families.

## Etiology

Iron deficiency comes about either as a late manifestation of prolonged negative iron balance or because of failure to meet an increased physiologic need for iron. The normal mechanisms for maintaining iron balance are discussed in Chapter 4. Factors leading to negative iron balance or to increased requirements are listed in Table 17-3 and illustrated in Figure 17-1.

## Diet

The normal daily iron requirement for adult men is 5 to 10 mg and for adult women,

7 to 20 mg.<sup>7</sup> The amount of iron in the diet bears a rough relation to caloric content; in the United States the diet contains about 6 mg iron per 1000 calories. From these data it may be estimated that the average man consumes more iron than he needs but that many sedentary women subsist on an iron intake that is at best marginal. Thus, fortification of the female diet appears justified. Currently, in the United States about 2.7 mg iron are added to 100 g flour (in Great Britain, 1.6 mg/100 g), but such small amounts have little effect on total intake.<sup>104</sup> Higher levels of food supplementation (9.0 mg/100 g) have been proposed<sup>52</sup> but have not yet gained complete acceptance because it is unknown whether they would increase the risk of iron overload in men.<sup>69</sup>

Because of their larger iron stores and

comparative adequacy of their diets, iron deficiency is almost never seen in American males as a result of diet alone. Exceptions to this rule are so rare as to justify the reporting of a single case.<sup>127</sup> No doubt, the inadequacy of female diets partially explains the frequency with which latent deficiency occurs in women. Even in women, however, some etiologic factor in addition to poor diet usually is necessary before overt anemia develops.<sup>89</sup>

The situation is different in countries where poverty,<sup>72</sup> war,<sup>73</sup> unwise agricultural practices,<sup>123</sup> or religious and social tenets<sup>141</sup> have led to unusually deficient diets. The average diet of a group of women of the poor classes in Scotland was found to supply only 2.5 mg of iron per day. In Norway, where the diet supplies only about 4 mg/1000 calo-

grown in it were low in iron content,<sup>50</sup> hypochromic anemia was found to be common.

The role of diet and other factors in the development of iron deficiency in infants is discussed on page 645.

### Impaired Absorption

Histamine-fast *achlorhydria* is common in iron-deficient subjects (Table 17-3), but this finding may be a result of the deficiency as well as a factor in its development.<sup>96</sup> In Chapter 4, it was pointed out that gastric acid facilitates absorption of ferric iron and food iron, but has little effect on heme iron or ferrous iron.

Iron-deficiency anemia is a frequent complication following *gastric operations*, including total gastrectomy,<sup>51</sup> partial gastrectomy,<sup>53,54,90,92,111</sup> and vagotomy with gastroenterostomy.<sup>68</sup> Reduction in gastric acidity is only one factor in the impaired iron absorption that follows such operations. Other gastric secretions essential to iron absorption may be lost.<sup>113</sup> Also, since the most active sites of iron absorption are in the duodenum, the rapid intestinal transit that follows loss of the reservoir function of the stomach may lead to decreased absorption. For the same reason, iron deficiency is more common when the duodenum is surgically bypassed, as in Billroth II or Polya procedures, than when the normal channel is preserved.<sup>53</sup> Finally, recurrent bleeding as well as increased sloughing of iron-containing epithelial cells may contribute to the development of postgastrectomy anemia.<sup>138</sup>

In addition to gastrectomy, other defects in the gastrointestinal tract may lead to malabsorption of iron and contribute to the development of iron deficiency. Thus, the anemia associated with adult *celiac disease* (gluten sensitivity, sprue, idiopathic steatorrhea) is often hypochromic rather than megaloblastic;<sup>60,83,101</sup> in fact, iron-deficiency anemia may be the initial and dominant manifestation of celiac disease, with steatorrhea detectable only by laboratory studies.<sup>101</sup> Although iron absorption is usually increased in iron-deficient subjects, severe defi-

rites, a high frequency of anemia in males between 15 and 19 and above 50 years of age and in women from maturity until menopause was attributed to iron deficiency.<sup>115</sup> In regions where the soil and the vegetables

Fig 17-1. Factors concerned in the development of iron-deficiency anemia

ciency in infants was found to be associated with impaired iron absorption.<sup>102</sup> A similar defect could be induced experimentally in weanling dogs. The defect, which was corrected by iron repletion, was thought to result from reduced activity of mucosal iron enzymes such as cytochrome oxidase. Malabsorption of other nutrients, such as fat and D-xylose, may also occur in severely iron-deficient infants.<sup>84</sup>

*Pica* refers to the habitual ingestion of unusual substances, the most common of which is earth or clay (geophagia). Laundry starch (amylophagia)<sup>80</sup> and ice (pagophagia)<sup>86</sup> are others. Although pica may be a manifestation of iron deficiency and may be relieved when the condition is treated,<sup>105</sup> among certain cultural groups pica is practiced compulsively for reasons rooted in custom, folklore, or superstition.<sup>67</sup> In the United States the habit appears to be particularly common among Negro women, especially when pregnant, in the South and West, but also in New York City.<sup>126</sup> It is also practiced by natives of Turkey,<sup>116,129</sup> Egypt,<sup>120</sup> and Iran.<sup>120</sup> Iron deficiency is a common complication of both

clay-eating and starch-eating.<sup>80,109,126</sup> Clay can behave in the gut as an ion exchange resin and interfere with iron absorption. Normal subjects, who absorbed 27% of a 5-mg iron dose, absorbed only 2% when Turkish clay was ingested with the iron. Similarly, iron-deficient subjects absorbed 46% of the iron, and only 6% with Turkish clay ingestion.<sup>110</sup> Other clays also inhibited absorption, but to a lesser degree. Laundry starch does not interfere directly with iron absorption<sup>80</sup>; however, it is an almost pure carbohydrate with a very low iron content. When it is consumed in large quantities to the exclusion of other foods, an extremely deficient diet results.<sup>126</sup> In Iran, Egypt, and Turkey, geophagia has been implicated in a syndrome consisting of iron-deficiency anemia, hepatosplenomegaly, hypogonadism, and dwarfism.<sup>120,129</sup> Such patients probably are deficient in zinc as well as iron.

### Blood Loss

Blood loss is by far the most important cause of iron-deficiency anemia. It is impor-

ries, a high frequency of anemia in males between 15 and 19 and above 50 years of age and in women from maturity until menopause was attributed to iron deficiency.<sup>115</sup> In regions where the soil and the vegetables

grown in it were low in iron content,<sup>50</sup> hypochromic anemia was found to be common.

The role of diet and other factors in the development of iron deficiency in infants is discussed on page 645.

## Impaired Absorption

Histamine-fast *achlorhydria* is common in iron-deficient subjects (Table 17-3), but this finding may be a result of the deficiency as well as a factor in its development.<sup>66</sup> In Chapter 4, it was pointed out that gastric acid facilitates absorption of ferric iron and food iron, but has little effect on heme iron or ferrous iron.

Iron-deficiency anemia is a frequent complication following *gastric operations*, including total gastrectomy,<sup>51</sup> partial gastrectomy,<sup>53,66,90,92,111</sup> and vagotomy with gastroenterostomy.<sup>68</sup> Reduction in gastric acidity is only one factor in the impaired iron absorption that follows such operations. Other gastric secretions essential to iron absorption may be lost.<sup>113</sup> Also, since the most active sites of iron absorption are in the duodenum, the rapid intestinal transit that follows loss of the reservoir function of the stomach may lead to decreased absorption. For the same reason, iron deficiency is more common when the duodenum is surgically bypassed, as in Billroth II or Polya procedures, than when the normal channel is preserved.<sup>53</sup> Finally, recurrent bleeding as well as increased sloughing of iron-containing epithelial cells may contribute to the development of postgastrectomy anemia.<sup>138</sup>

In addition to gastrectomy, other defects in the gastrointestinal tract may lead to malabsorption of iron and contribute to the development of iron deficiency. Thus, the anemia associated with adult *celiac disease* (gluten sensitivity, sprue, idiopathic steatorrhea) is often hypochromic rather than megaloblastic<sup>69,88,101</sup>; in fact, iron-deficiency anemia may be the initial and dominant manifestation of celiac disease, with steatorrhea detectable only by laboratory studies.<sup>101</sup>

Although iron absorption is usually increased in iron-deficient subjects, severe defi-

Fig 17-1 Factors concerned in the development of iron-deficiency anemia

ciency in infants was found to be associated with impaired iron absorption.<sup>102</sup> A similar defect could be induced experimentally in weanling dogs. The defect, which was corrected by iron repletion, was thought to result from reduced activity of mucosal iron enzymes such as cytochrome oxidase. Malabsorption of other nutrients, such as fat and D-xylose, may also occur in severely iron-deficient infants.<sup>84</sup>

*Pica* refers to the habitual ingestion of unusual substances, the most common of which is earth or clay (geophagia). Laundry starch (amylophagia)<sup>80</sup> and ice (pagophagia)<sup>66</sup> are others. Although pica may be a manifestation of iron deficiency and may be relieved when the condition is treated,<sup>105</sup> among certain cultural groups pica is practiced compulsively for reasons rooted in custom, folklore, or superstition.<sup>67</sup> In the United States the habit appears to be particularly common among Negro women, especially when pregnant, in the South and West, but also in New York City.<sup>126</sup> It is also practiced by natives of Turkey,<sup>116,129</sup> Egypt,<sup>120</sup> and Iran.<sup>120</sup> Iron deficiency is a common complication of both

clay-eating and starch-eating.<sup>80,109,126</sup> Clay can behave in the gut as an ion exchange resin and interfere with iron absorption. Normal subjects, who absorbed 27% of a 5-mg iron dose, absorbed only 2% when Turkish clay was ingested with the iron. Similarly, iron-deficient subjects absorbed 46% of the iron, and only 6% with Turkish clay ingestion.<sup>110</sup> Other clays also inhibited absorption, but to a lesser degree. Laundry starch does not interfere directly with iron absorption<sup>80</sup>; however, it is an almost pure carbohydrate with a very low iron content. When it is consumed in large quantities to the exclusion of other foods, an extremely deficient diet results.<sup>126</sup> In Iran, Egypt, and Turkey, geophagia has been implicated in a syndrome consisting of iron-deficiency anemia, hepatosplenomegaly, hypogonadism, and dwarfism.<sup>120,129</sup> Such patients probably are deficient in zinc as well as iron.

#### Blood Loss

Blood loss is by far the most important cause of iron-deficiency anemia. It is impor-

tant not only because of its frequency (Table 17-3), but also because the accurate detection, precise diagnosis, and proper management of the bleeding lesion may be of far greater importance to the ultimate well-being of the patient than repletion of his iron stores. For the purpose of estimating the effect of blood loss on iron balance, 1.0 ml of blood may be considered to contain about 0.5 mg iron. Thus, if an average diet is consumed, a steady blood loss of as little as 3 to 4 ml/day (1.5 to 2 mg iron) can result in negative iron balance.

### Gastrointestinal Bleeding

Gastrointestinal bleeding is by far the most common cause of iron deficiency in adult men and is second only to excessive menstrual blood loss as a cause in women. Any hemorrhagic lesion of the alimentary tract may cause iron deficiency. Those most likely to do so are the kind that are associated with occult bleeding or with the steady loss of small amounts of blood. Such lesions may go unnoticed or may be tolerated until the symptoms of anemia supervene. The relative frequency of the bleeding lesions leading to iron deficiency in a series of 317 adults<sup>60,144</sup> is given in Table 17-3. The list is not meant to be comprehensive since many other, less common lesions have been reported in association with isolated cases of iron-deficiency anemia.

*Hemorrhoids* are certainly one of mankind's commonest ailments, affecting more than a quarter of the population.<sup>94</sup> Two thirds of patients with hemorrhoids experience rectal bleeding, usually of a kind that is obvious to the patient since the blood streaks the outside of the stool or stains the water in the toilet bowl. Nevertheless, in one group of over 20,000 patients,<sup>62</sup> 80% allowed a year to elapse before seeking medical attention, and 32% had known of their disease for more than 10 years. A proportion of these patients become accustomed to the periodic loss of small amounts of blood, and gradual depletion of their iron stores occurs without their becoming unduly alarmed. Despite the frequency

with which hemorrhoids are associated with iron-deficiency anemia (Table 17-3), the clinician should be reluctant to accept them as the only bleeding lesions until a careful investigation has been made; hemorrhoids may obscure another, less obvious lesion elsewhere in the alimentary tract.

*Duodenal and gastric ulcers* are by far the most common cause of upper gastrointestinal bleeding,<sup>117</sup> which may be massive or occult. About 25% of patients with bleeding ulcers give no history of prior symptoms. When 1000 patients with ulcers were followed prospectively, 449 of them had 652 episodes of hemorrhage in 66,580 patient-months.<sup>117</sup> About half of these episodes of bleeding did not require blood transfusion and, therefore, were of the pattern that may result in iron depletion.

Although *aspirin* is considered by most laymen to be an innocuous drug, the frequency with which it causes blood loss is becoming apparent.<sup>128</sup> At a daily dose of 2 to 6 g of aspirin, 70% of patients were detected to have gastrointestinal bleeding at an average rate of 5 ml/day.<sup>132</sup> After seven days' treatment with only 2 aspirin tablets per day, or an equivalent dose of other salicylate-containing medications, excessive blood loss (1 to 4.5 ml/day) was detected.<sup>57</sup> The salicylate-induced lesion is probably an erosive gastritis.<sup>128,139</sup>

Iron-deficiency anemia occurs in about 15% of patients with *esophageal hiatal hernia*.<sup>143</sup> Anemia is particularly common (30%) with the paraesophageal variety and is more common when the hernias are large. Anemia may be the presenting manifestation and may occur even when there are no dyspeptic symptoms.<sup>93,143</sup> The average daily blood loss in 19 anemic patients with hiatal hernia was found to be 15 ml.<sup>93</sup> The reason for the bleeding remains controversial; reflux esophagitis is one possibility, but trauma to the gastric mucosa at the neck of the hernial sac is a more likely one.<sup>143</sup>

Although bleeding from colonic diverticula was once considered unusual, more recent studies have demonstrated a 5 to 8% incidence of hemorrhage due to *diverticulosis* and

15 to 25% due to diverticulitis.<sup>98</sup> Usually the blood loss is of mild degree and intermittent, and may resemble the pattern of hemorrhoidal bleeding. As with the latter, a careful investigation for other sources of intestinal blood loss must be made in order to exclude the possibility of neoplasm.

Iron-deficiency anemia may be the first sign of a neoplasm of the gastrointestinal tract, and the anemia may lead to its discovery in an operable stage. Carcinoma of the cecum often is clinically silent until anemia occurs. Less frequently, in carcinomas of other parts of the colon as well as of the stomach and the ampulla of Vater, iron-deficiency anemia may be the only initial symptom.

A survey of 32 patients with ulcerative colitis found 26 of them (81%) to have iron-deficiency anemia.<sup>95</sup> Average fecal blood loss of 6 to 25 ml per day was noted in five patients who were moderately anemic with relatively mild symptoms of colitis.

An important source of gastrointestinal blood loss in tropical areas is infection with the hookworm, *Necator americanus* or *Ancylostoma duodenale*.<sup>124</sup> Hookworm affects some 20% of the world's population.<sup>144</sup> The infection is endemic in a zone extending from the southern United States to northern Argentina in the Western Hemisphere, as well as in Mediterranean countries, South Asia, and Africa. The worms attach to the upper small intestine and suck blood from the host. The amount of blood lost is proportional to the number of worms harbored, which in turn can be estimated by the fecal excretion of hookworm eggs. On the average, each worm accounts for the loss of about 0.05 ml blood per day.<sup>81,123</sup> Female subjects harboring more than 100 worms (5 ml/day blood loss) and male subjects harboring more than 250 (12.5 ml/day blood loss) tend to become anemic.<sup>124</sup> The daily blood loss may be as great as 250 ml. Other factors affecting iron balance will determine whether the mildly infected individual becomes anemic. Deficient diet, repeated pregnancies, and achlorhydria have been found to be contributory factors in studies of hookworm anemia made

in Puerto Rico<sup>123</sup> and in Brazil.<sup>70,119</sup> It is significant that, among hookworm carriers in Argentina, those who consumed much meat were not anemic. In an endemic zone in Venezuela, 30% of noninfected individuals were anemic as compared with 46% of infected individuals.<sup>124</sup> Thus, the anemia in 16% could reasonably be attributed to the parasite.

At one time it was widely believed that hookworm anemia is due to elaboration of a toxin. No such mysterious concept is necessary. The anemia possesses all the characteristics of iron deficiency and can be relieved with iron therapy whether the worms are removed or not.<sup>70</sup>

Causes of gastrointestinal blood loss which are unique to infancy are discussed in a later section of this chapter (page 648).

### Reproductive Tract

Excessive menstrual blood loss is the most common single cause of iron deficiency in women (Table 17-3). In healthy, hematologically normal women, menstrual blood flow averages about 35 ml per menstrual period, and the upper limit of normal is about 80 ml per period.<sup>85,95</sup> Although flow varies considerably among different women, it is remarkably constant from one period to the next in the same individual.<sup>85</sup> In Swedish women with a dietary intake of about 10 mg iron per day, 67% of women with menstrual blood loss exceeding 80 ml/period were anemic.<sup>85</sup> In another study, British women with iron-deficiency anemia were found to lose 85 ml per period.<sup>95</sup> In contrast, however, a better nourished Canadian population tolerated flows greater than 80 ml per period without overt anemia or hypoferrremia.<sup>96</sup>

It is difficult to estimate menstrual blood loss by history, and many women are poor judges of the normality of their flow. Forty-one percent of women with blood loss exceeding 80 ml considered their periods to be "moderate" or even "scanty," and conversely 14% of women with flows less than 20 ml considered theirs to be "heavy."<sup>85</sup> Even medically sophisticated women may lose

more than 200 ml without realizing that their periods are unusual.<sup>112</sup> Thus, an adequate medical history in an anemic woman must contain a detailed description of the events during each menstrual period. Any of the following are indications of excessive menstrual flow: (1) inability to control flow with tampons alone, (2) use of more than 12 pads per period or four per day, unless the patient is unusually fastidious, (3) passage of clots, especially if they are larger than about 2 cm in diameter or if they persist after the first day, and (4) period duration exceeding seven days.

### *Blood Donation*

Regular blood donation may be an important source of iron loss. Each "unit" of blood donated contains about 250 mg of iron, often enough to exhaust the stores of a "normal" woman. Three or four such donations would exhaust the stores of a normal man. At one time, it was not unusual to encounter patients with iron-deficiency anemia caused only by frequent blood donations.<sup>54</sup> With precautions taken by present-day blood banks, such occurrences are unlikely. Still, blood donation would be expected to precipitate anemia in a patient with latent deficiency.

### *Hemoglobinuria*

Unnary iron losses averaging 1.8 to 7.8 mg/day accompany paroxysmal nocturnal hemoglobinuria.<sup>87</sup> Consequently, this rare disorder (Chapter 29) often is complicated by hypoferrremia and hypochromic anemia.<sup>87,100</sup> Hemoglobinuria in other disorders, such as the erythrocyte fragmentation syndromes associated with prosthetic cardiac valves (Chapter 28), also may be complicated by iron deficiency.<sup>122,123</sup>

### *Factitious Anemia*

An unusual cause of iron deficiency is self-induced blood-letting.<sup>59,71</sup> Almost all the instances of such anemia have been reported in unmarried women in paramedical occupa-

tions. Blood was removed by venipuncture, or bleeding was induced by injuring preexisting hemorrhoids or by laceration of the gastrointestinal tract with such instruments as knitting needles, or by means which remained obscure. In general, the women with this form of blood loss were described as hyperactive, obsessive, and intelligent and as displaying unusual hostility or contempt toward the medical profession.

### *Pulmonary Iron Sequestration*

Idiopathic pulmonary hemosiderosis<sup>75,108,134</sup> is characterized by repeated episodes of multifocal hemorrhages from alveolar capillaries. Iron in the shed blood is converted to hemosiderin by pulmonary macrophages, but cannot be reutilized for hemoglobin synthesis.<sup>108</sup> As a result, there is a steady sequestration of the body iron in the lungs, and iron-deficiency anemia almost invariably accompanies the disease. Frequently, anemia is the initial and only symptom. Other manifestations include cough, transient pulmonary infiltrates, and, after several years, pulmonary fibrosis, dyspnea, and digital clubbing. Pulmonary hemorrhage with hemosiderosis and iron-deficiency anemia also are common findings in Goodpasture's syndrome.<sup>58</sup>

### *Hereditary Hemorrhagic Telangiectasia*

This uncommon disorder is characterized by recurrent hemorrhages from the nose, gastrointestinal tract, and other sites (Chapter 36). Iron-deficiency anemia, sometimes very difficult to control, is an important complication of the illness.

### *Disorders of Hemostasis*

These illnesses rarely cause chronic blood loss leading to iron deficiency. As a rule the bleeding is acute, and treatment often involves replacement of blood as well as the coagulation factors which are lacking (Chapters 37 and 38).

### Idiopathic Hypochromic Anemia

The frequency with which iron-deficiency anemia occurs in the absence of a documented etiologic factor depends to some extent on the thoroughness of the investigation. No cause could be found at initial evaluation in 92 of 371 patients with iron-deficiency anemia.<sup>60</sup> However, a source of blood loss was later found in 28, leaving 64 (17%) to whom the label "idiopathic hypochromic anemia" could reasonably be applied. In this group the age, sex, and clinical manifestations were no different than in the patients with known causes. Thus, there is little justification to regard this group as representing a distinct entity. Instead, their underlying disease should be considered to be either in remission or not detectable at the time of examination.<sup>60,144</sup>

### Infancy

Some of the etiologic factors leading to iron deficiency in infancy are unique to this period of life and deserve special consideration (Table 17-4).

#### Decreased Total Body Iron at Birth

Body iron concentration at birth averages 78 mg per kg body weight (range 65 to 90 mg/kg) of which about 60 mg are accounted for as circulating hemoglobin and the rest is in stores.<sup>99</sup> Similar concentrations are found throughout fetal development, so that there is a roughly linear relation between body iron and body weight. Newborn babies in the

upper range of normal birth weights have 80% more iron than those in the lower range.<sup>63</sup> In a series of 272 infants the most important single factor predisposing to iron deficiency was *low birth weight*.<sup>145</sup> The incidence of severe anemia in infants whose birth weights exceeded 4000 g was extremely low whereas 80% of infants with a blood hemoglobin less than 5 g/dl were premature or weighed less than 3000 g at birth. In another study, 26.5% of a group of premature infants developed anemia with a blood hemoglobin of less than 9.0 g/dl.<sup>131</sup> The incidence dropped to 6.4% when feeding formulas were supplemented with iron.

Iron deficiency is more common in *twins* than in infants born singly. One factor is the tendency of twins to be smaller at birth. Another is the occurrence of placental transfusion of one monozygotic twin to another. Such an event can lead to a marked difference between the blood hemoglobin values of twins.<sup>82,121</sup> In a study of 130 sets of monozygotic twins, serious twin transfusion occurred in 19 (15%). In only four of these did both twins survive.<sup>121</sup> The late occurrence of iron deficiency in one member of a set of twins might represent a milder form of the same phenomenon.<sup>145</sup>

One of the important influences on iron in the newborn is easily controlled by the physician, namely, the time at which the umbilical cord is clamped at delivery. As much as 100 ml of fetal blood may remain in the placenta with early clamping of the cord.<sup>140</sup> Cord clamping delayed for only three minutes can result in a 58% increase in red cell volume.<sup>149</sup> Although the newborn has no immediate need for these erythrocytes the iron they contain can later be utilized to meet the demands of growth.

The influence of *maternal iron deficiency* on the body iron of the newborn is controversial, but the preponderance of evidence suggests that the depletion of maternal iron has little or no effect. In one study, infants born to mothers with blood hemoglobin concentrations less than 7 g/dl were found to have normal hemoglobin levels at birth, but tended to become anemic toward the end

**Table 17-4. Etiology of Iron Deficiency in Infancy**

- |   |                                    |
|---|------------------------------------|
| A | Decreased total body iron at birth |
| 1 | Low birth weight, prematurity      |
| 2 | Twins                              |
| 3 | Early clamping of umbilical cord   |
| 4 | Maternal iron deficiency           |
| 5 | Fetomaternal hemorrhage            |
| B | Growth                             |
| C | Inadequate diet                    |
| D | Blood loss                         |

of the first year of life.<sup>136</sup> Control groups of infants born to nonanemic or iron-treated mothers did not become anemic. In this study, environmental factors may not have been fully controlled; the mothers who became anemic may have been drawn from lower socioeconomic groups and may have fed their offspring an iron-deficient diet.<sup>61,103</sup> In another study, however, the red cell mass of infants born to severely anemic mothers was found to be 19% below that of a normal group.<sup>133</sup> In contrast, other investigators have found no difference between the hemoglobin values in infants of anemic and in those of nonanemic mothers either at birth or later.<sup>103,146</sup> Furthermore, iron supplementation during pregnancy had no effect on the subsequent development of iron deficiency in the infant.<sup>103,137</sup> These observations are consistent with studies made in animals which demonstrate that iron is transported across the placenta against a gradient, even at the expense of maternal iron stores.<sup>79,107</sup>

**FETOMATERNAL TRANSFUSION.** The transplacental passage of fetal erythrocytes into the maternal circulation is a physiologic event.<sup>65,106</sup> In about half of a series of 223 pregnant women, small amounts (mean, 0.4 ml) of fetal blood could be identified in the circulation between 21 and 42 weeks of gestation.<sup>106</sup> In the immediate postpartum period, fetal erythrocytes also were demonstrated in 50% of mothers; in 10% the fetal losses were "large" (0.5 to 40 ml) and in 1% they were "massive" (greater than 80 ml), usually resulting in overt anemia in the newborn.<sup>65</sup> In several instances, fetomaternal transfusion, probably over a prolonged time interval, has resulted in iron deficiency with hypochromic, microcytic anemia in the newborn.<sup>78,83,118</sup> In other cases, massive fetomaternal hemorrhage near term has led to hemorrhagic anemia, shock, or hydrops fetalis in the affected newborns.<sup>106,118</sup> It is likely that milder degrees of hemorrhage lead to reduced iron reserves in a proportion of newborns, thereby increasing the probability of the later development of anemia; however, the frequency of such occurrences cannot be estimated from presently available data.

## Growth

In the absence of disease, requirements of an adult male for iron vary little. In infancy, childhood, and adolescence, on the other hand, because of the increased needs of rapidly growing tissues, the requirements for iron are relatively great. The most rapid relative growth rates in human development occur in the first year of life. During this period, body weight and blood volume approximately triple, and the circulating hemoglobin mass nearly doubles (Table 17-5).<sup>131</sup> Still greater relative growth occurs in premature infants and others with low birth weights. A premature weighing 1.5 kg may increase his weight and blood volume sixfold, and may triple the circulating hemoglobin mass in one year (Table 17-5). If this rapid expansion of circulating hemoglobin is to occur, a large amount of iron is required. It has been aptly stated that "the infant bleeds into his own increasing blood volume."<sup>89</sup>

The relatively slower rates of growth in the ages from 1 to 12 years require a positive iron balance of about 0.2 to 0.3 mg per day. The growth spurt that occurs between 11 and 14 years of age requires a positive balance of about 0.5 mg/day in girls and 0.6 mg/day in boys.<sup>7</sup> Toward the end of this period the onset of menstruation occurs in girls, and their requirements then become those of adult women. The effects of age on iron requirements are shown in Figure 17-2.

## The Diet in Infancy and Childhood

Since unsupplemented milk is a poor source of iron (about 0.075 mg Fe/100 g milk),<sup>63</sup> most infants receive little iron in their diet until solid foods are introduced. Of the latter, the most important are iron-enriched cereals, which supply about 80% of the average infant's dietary iron during the first six months of life.<sup>64</sup> Recommended dietary iron intake for infants during the first year of life is about 6 mg per day<sup>63</sup> or 1.5 mg/kg body weight per day.<sup>7,131</sup> These are the highest requirements in relation to food intake that occur throughout life and are difficult to achieve without iron supplements,

Table 17-5. Iron Balance during the First Year of Life\*

	Full Term Infant		Premature Infant	
	Birth	1 Year	Birth	1 Year
Weight (kg)	3.3	10.5	1.5	9.5
Blood hemoglobin (g/dl)	20.0	12.3	20.0	12.3
Blood volume (ml)	290	800	135	720
Total hemoglobin (g)	58	98	27	89
Hemoglobin Iron (mg)	198	335	90	300
Storage & Tissue Iron (mg)	60	73	27	67
Total Body Iron (mg)	258	408	117	367
Net positive iron balance (mg/yr)	150		250	
iron balance (mg/day)	0.4		0.7	

\*Modified from Schulman<sup>131</sup>

especially if solid foods are introduced relatively late. Dietary requirements fall to about 1 mg/kg when the child is one year of age and 0.5 mg/kg when he is 18 months old.<sup>131</sup> Thereafter, the estimated total requirement of children is 4 to 10 mg/day, the higher figure allowing for establishment of stores. Adolescents require 10 to 20 mg/day.<sup>7</sup>

By far the most common cause of an inade-

quate diet in infancy is excessive dependence on milk.<sup>74,147</sup> Some mothers allow their children to use the bottle as a pacifier and constant companion, and the infants become addicted ("milkoholics"). In one study, inadequate diet was considered to be the only factor in the development of iron deficiency in 20 of 55 infants<sup>74</sup>; it was uncommon in this series to find iron deficiency resulting

Fig. 17-2. Iron requirements in males and females of various ages. The greatest requirements in relation to food intake occur during infancy. During childhood, requirements are the same in both sexes. The adolescent growth spurt leads to a further increase in iron needs, more so in the male than in the female. Thereafter, with the onset of menstruation, adult female requirements exceed those of the male.

from defective stores at birth unless the diet was also inadequate. "Bakima disease" was attributed to the practice of the Uganda tribe of feeding children almost exclusively on a diet of cows' milk.<sup>97</sup>

### Blood Loss in Infancy

Occult hemorrhage, often without obvious anatomic lesions, has been observed in iron-deficient infants by a number of investigators.<sup>91,112</sup> The process is often accompanied by diffuse disease of the bowel with protein-losing enteropathy and impaired absorption of several nutrients.<sup>81,91</sup> Generalized hypoproteinemia may be observed, along with hypocupremia due to ceruloplasmin loss.<sup>130</sup> Whether this syndrome is a cause or the result of iron deficiency is disputed.<sup>77</sup> In some instances, the abnormalities appear to have been corrected by iron treatment alone.<sup>114</sup> On the other hand, considerable evidence that the disorder results from hypersensitivity to a heat-labile protein in cows' milk has been reported.<sup>112,115</sup> The daily loss of 1 to 4 ml of blood, along with increased serum albumin turnover, was observed while fresh cows' milk was being consumed, and these abnormalities ceased abruptly when heat-treated or soybean-protein feeding formulas were substituted. Furthermore, in infants in whom fresh cows' milk was introduced into the diet at age two months, iron deficiency was considerably more common

than in those receiving prepared formulas during the entire first year of life.<sup>148</sup>

An uncommon cause of blood loss, almost unique to infancy, is bleeding from Meckel's diverticulum.<sup>135</sup> Diagnosis may be difficult prior to abdominal exploration.

### Pregnancy and Lactation

Pregnancy constitutes a major drain on the iron reserves of women of childbearing age. Each pregnancy results in an average loss to the mother of 680 mg of iron (Table 17-6), the equivalent of 1300 ml blood. An additional 450 mg of iron must be available to meet the needs of an expanded blood volume in pregnancy. This does not represent a loss because after delivery the iron is returned to stores, but it must be available during the pregnancy or iron-deficiency anemia will supervene.

Prorated over the full term of pregnancy, the iron requirement amounts to 2.5 mg/day (Table 17-6). Since most of the loss occurs during the third trimester, the requirement is small early in pregnancy and rises to as much as 3 to 7.5 mg/day in the third trimester (Fig. 17-3). These amounts are much greater than can be absorbed from even the best of diets; hence, adequate prenatal care requires iron supplementation. In the absence of supplements, iron-deficiency anemia often occurs, usually becoming apparent in the third trimester.<sup>76</sup>

Table 17-6. Iron Balance in Pregnancy<sup>7</sup>

Iron	Amount (mg)	
	Mean	Range
Lost to fetus	270	(200-370)
Lost in placenta and cord	90	(30-170)
In blood lost at delivery	150	(90-310)
Normal body iron loss	170	(150-200)
Added to expanded red cell mass	450	(200-600)
<b>Total</b>	<b>1130</b>	<b>(670-1650)</b>
Returned to stores when red cell mass contracts after delivery	450	(200-600)
<b>Net Loss</b>	<b>680</b>	<b>(470-1050)</b>
mg/9 mo		
mg/day	2.5	(1.7-4.0)

Fig. 17-3. Daily iron requirements in the adult female during pregnancy and postpartum. The requirement includes iron lost from the body and iron for the fetus, for the enlarging red cell mass during pregnancy, and for lactation after birth of the child (From Bothwell and Finch,<sup>61</sup> courtesy of the authors and Little, Brown & Co.)

Lactation results in a daily iron loss of about 0.5 to 1 mg. Since normal menstruation is usually inhibited while breast feeding continues, iron requirements in the lactating woman approximate those of the menstruating woman (Fig. 17-3).

## Clinical Manifestations of Iron Deficiency

Anemia is not a disease; it is a sign of disease. Iron-deficiency anemia is no exception to this rule. In some cases, iron-deficiency anemia is discovered as an incidental finding and the presenting signs and symptoms are related to the disease which led to the deficiency (eg, peptic ulcer). In other cases, manifestations both of the underlying disease and of iron deficiency itself are found. A final group of patients seeks medical attention for symptoms of iron deficiency alone, and the disease process leading to the deficiency is obscure. In the discussion to follow, only the manifestations of iron deficiency will be dealt with. The possible underlying diseases have been discussed in the previous section.

### Age and Sex

In adults, iron deficiency is considerably more common in women than in men (Fig. 17-4), for reasons already discussed. In women, the disorder is seen most frequently during the reproductive years, whereas in men the incidence is relatively high at adolescence, low during young adulthood, and increases thereafter with age (Fig. 17-4).

In infancy, iron deficiency occurs with equal frequency in both sexes. It is usually detected between 6 and 20 months of age<sup>74,181</sup>; the peak incidence occurs at a younger age in infants born prematurely than in those born at term (Fig. 17-5).

### Mode of Presentation

The onset of iron-deficiency anemia is almost invariably insidious and the progression of symptoms is gradual. As a result, patients accommodate remarkably well to advancing anemia and may delay a visit to their physician for prolonged periods: an average of 8 years in the 1930's<sup>27</sup> and in more recent times an average of 3.3 years in women and 1.7 years in men.<sup>60</sup>

Most patients seek medical attention be-

Fig 17-4 Age and sex of 371 adults with iron-deficiency anemia (From Beveridge et al,<sup>60</sup> courtesy of the authors and Oxford University Press)

cause of symptoms of anemia alone. This was true in 63% of 371 patients.<sup>60</sup> Another 16% visited the physician because of symptoms of the disease causing the anemia. In the remaining 21%, anemia was discovered upon evaluation of an unrelated complaint.

#### Fatigue and Other Symptoms of Anemia

Although fatigue is a common complaint of patients who are anemic, it is also common among those who are not. When symptoms in a diseased population are compared with those in a healthy one, mild to moderate iron-deficiency anemia appears to be completely asymptomatic. In the range of 8 to 12 g/dl hemoglobin concentration, there was no correlation between the degree of anemia and the intensity of any of the following symptoms: fatigue, irritability, palpitations, dizziness, breathlessness, or headache.<sup>13</sup> Furthermore, in a controlled study, treatment with iron in amounts sufficient to increase the hemoglobin an average of 2.3 g/dl (from 10.6 to 12.9 g/dl) resulted in no

greater improvement in any of the above symptoms than did treatment with a placebo.

Obviously, at some point, the hemoglobin reaches a level that produces symptoms. A carefully controlled study to determine that level has not been carried out. However, indirect evidence suggests that at least a significant proportion of patients seek medical attention for symptoms of anemia at hemoglobin levels between 7 and 8 g/dl. The average hemoglobin value at first visit in 371 patients was 7.6 g/dl,<sup>60</sup> and 80% of the patients had manifestations that were ascribed to anemia. Patients may develop severe degrees of anemia, with hemoglobin values as low as 4 g/dl, with remarkably few complaints. When signs and symptoms do develop, they usually are manifestations of the cardiovascular adjustments to anemia. These have been discussed in Chapter 13.

In sharp contrast to the conclusion of the studies cited above is the suggestion that even latent iron deficiency, ie, iron deficiency without any anemia at all, may result in fatigue.<sup>3</sup> A group of 44 oonanemic women complaining of fatigue were treated both with

iron and with placebo in random order. Symptomatic improvement on iron was significantly better than on placebo, but only in women whose iron stores were depleted. Others have been unable to confirm this observation.<sup>9,10,13</sup> It seems possible that the patients knew when they received iron because of the well-known change in stool color which accompanies such therapy. If change in color occurred, the placebo effects on fatigue could have been dramatic; in one study, 47% noted improvement in fatigue with placebo treatment alone.<sup>13</sup>

### Epithelial Tissues

Certain abnormalities found in iron-deficient patients are characterized by defective structure or function of epithelial tissues.

Especially affected are the nails, the tongue and mouth, the hypopharynx, and the stomach. These epithelial lesions tend to occur together in the same patients at the same time,<sup>60</sup> but may also occur as isolated findings. Less well established are effects on the skin, hair, and nose.

The incidence of epithelial abnormalities in a large group of iron-deficient, anemic patients studied in England between 1941 and 1960 is given in Table 17-7.<sup>60</sup> These figures (the most recent available) do not differ greatly from those found in 1933 in a review of 260 patients from several parts of the world, including the United States.<sup>27</sup> It has been claimed<sup>34</sup> that the epithelial manifestations of iron deficiency now are uncommon in the United States. We tend to agree, but there is no good statistical evidence to

Fig. 17-5 Age distribution of 533 infants with iron-deficiency anemia. The illness occurs at a younger age in prematures than in full term infants (From Lovnic et al.,<sup>131</sup> courtesy of the authors and Australasian Medical Publishing Co.)

**Table 17-7. Incidence of Epithelial Lesions in Iron Deficiency**

Organ	Finding	Incidence <sup>a</sup>
Nails	Flattening	10%
	Koilonychia	18%
	Total abnormal	28%
Tongue	Sore tongue	11%
	Absence of filiform papillae	11%
	Lesser degrees of papillary atrophy	28%
	Total abnormal	39%
Mouth	Angular stomatitis	14%
Hypopharynx	Dysphagia	7%
Stomach	Achlorhydria	41%
	Gastritis†	74%
Nose	Ozena	0

<sup>a</sup>In 371 adult British patients seen from 1941-1960.<sup>60</sup>

†By gastric biopsy. The figures include superficial gastritis, atrophic gastritis and gastric atrophy. In controls, gastritis was found in 29% of biopsies.<sup>149</sup> Similar results have been reported by others.<sup>174</sup>

either support or refute the opinion. It is also of interest to note that the incidence of dysphagia is said to be very low in areas of East and Central Africa where iron deficiency is almost universal.<sup>177</sup>

### Nails

The fingernails may become brittle, fragile, or longitudinally ridged, but such findings are quite nonspecific. Alterations more typical of iron deficiency are thinning, flattening, and, finally, the development of *koilonychia*, concave or "spoon-shaped" nails (Fig. 17-6). *Koilonychia* has been thought to be rare in iron-deficient infants,<sup>183</sup> but out of 400 babies attending a well-baby clinic in West Virginia, 22 (5.5%) were found to have *koilonychia*, and at least 18 of these appeared to be iron deficient<sup>172</sup> (Fig. 17-7).

*Koilonychia*, while strongly suggestive of iron deficiency,<sup>144</sup> can develop with long repeated exposure to hot soapsuds and other caustic agents.<sup>162</sup> When *koilonychia* is associated with a variety of skin conditions, such

as fungal disease, the nails are likely to be irregularly pitted. ✓

### Tongue and Mouth

Atrophy of the lingual papillae, the most common of the epithelial changes (Table 17-7), may be accompanied by soreness or burning of the tongue, occurring either spontaneously or stimulated by food or drink, and by varying degrees of redness.<sup>60,141,176</sup> The filiform papillae over the anterior two thirds of the tongue are the first to atrophy, and may disappear completely. In severe cases, fungiform papillae also may be affected, leaving the tongue completely smooth and waxy or glistening in appearance<sup>176</sup> (Fig. 17-8). A biopsy study confirmed the absence of filiform papillae in a proportion of iron-deficient patients and also demonstrated loss of keratohyalin granules in lingual epithelial cells.<sup>183</sup> These changes were reversed after one to two weeks of iron therapy.

Angular stomatitis is characterized by ulcerations or fissures at the corners of the mouth. In addition to iron deficiency, edentia, poorly fitting dentures, and other nutritional deficiencies contribute to the development of such lesions.<sup>60</sup>

### Dysphagia

The association of dysphagia, angular stomatitis, and lingual abnormalities with hypochromic anemia in middle-aged women was first described independently by Paterson<sup>185</sup> and by Kelly<sup>179</sup> in 1919. Vinson, in 1922, reported 69 similar cases and attributed the first description of the syndrome to apparently unpublished observations of Plummer.<sup>189</sup>

Patients with sideropenic dysphagia<sup>190</sup> (Paterson-Kelly syndrome,<sup>177</sup> Plummer-Vinson syndrome) note the usually gradual onset of dysphagia; they describe the site of the discomfort as being localized sharply to the area of the neck near the cricoid cartilage. They experience difficulty in swallowing solid foods and have little problem with liquids. If the patient is untreated the dysphagia

Fig 17-6 Fingernails of an iron-deficient adult (below) compared with those of a normal subject (From Rosenbaum and Leonard,<sup>127</sup> courtesy of the authors and *Annals of Internal Medicine*)

grows worse, and ultimately his diet becomes so restricted as to interfere with nutrition.

The most common anatomic lesion is a "web" of mucosa at the juncture between the hypopharynx and esophagus. These webs, which may be multiple, usually extend from the anterior wall into the lumen of the esophagus, but they may encircle the lumen completely, forming a cuff-like structure. In other patients a benign stricture, with or without a web, may be found; and the opening into the esophagus at the cricoid area may be reduced to the size of a pinhole or slit.<sup>144</sup>

Both webs and strictures can often be demonstrated by x rays of the lateral aspect

of the neck taken after barium swallow<sup>173,190</sup> (Fig. 17-9). Multiple exposures or cineradiography are required for optimal demonstration of these abnormalities. Radiologic findings in this syndrome in 55 Welsh patients, of which 53 were women, were as follows: 38 (69%) with webs, including five with two webs; six (11%) with benign stricture of the esophagus; five (9%) with carcinoma, presumably a late complication since all had had dysphagia for over 20 years; and seven (13%) with no demonstrable lesion.<sup>177</sup>

On biopsy, the webs appear to be constructed of normal epithelium with underlying loose connective tissue, in which there

Fig 17-7. Koilonychia in a 1½-year-old child with iron-deficiency anemia

Fig 17-8 Tongue of a patient with iron-deficiency anemia showing moderately severe papillary atrophy before therapy (A) and restoration after iron repletion (B) (Courtesy of RW Monto, Detroit Michigan)

may be a chronic inflammatory reaction.<sup>163,170</sup> In a small proportion, hyperchromatic nuclei and increased mitotic activity may be observed in the basal cell layer. Biopsy of the stricture demonstrates chronic, nonspecific inflammation and degeneration of striated muscle. Carcinoma in situ was found in 5% of biopsy studies.<sup>170</sup> Carcinoma in the postcricoid area as a late complication of the syndrome was described in the original reports of Paterson and Kelly.<sup>179,185</sup>

For relief of the dysphagia, it is usually necessary to rupture the webs and/or dilate the stenosis by means of bouginage. Reple-

tion of the iron stores will not, by itself, suffice.<sup>141</sup>

### *Stomach*

Gastric biopsy demonstrates the presence of "gastritis" in about 75% of patients with iron-deficiency anemia as compared to about 29% in controls.<sup>169,174</sup> Depending on the criteria used by various authors, the gastritis has been classified as "superficial," "mildly" to "severely" atrophic, or as "gastric atrophy." Such lesions are nonspecific and may be indistinguishable from those seen in association with pernicious anemia or occasionally in apparently normal, older adults (Chapter 15, page 606).<sup>182</sup> Most investigators have concluded that chronic gastritis of this sort produces few, if any, symptoms.

Associated with the gastritis are varying degrees of reduction in gastric secretion. With progression of gastric damage, there is loss of ability to secrete acid, pepsin, and intrinsic factor, in that order.<sup>144</sup> The proportion of iron-deficient patients found to have achlorhydria depends on the methods used to stimulate secretion. Thus, in early studies, an incidence as great as 80% was observed.<sup>28</sup> The data in Table 17-7 came largely from the use of single-dose histamine or Diágnex Blue testing. Of 70 patients subjected to the more stringent augmented histamine test, achlorhydria was found in only 16% and extreme hypochlorhydria in 7%. With this technique,<sup>144</sup> achlorhydria is most unusual in unselected hospital controls.

Of the same 70 patients, in 6% intrinsic factor secretion was impaired or absent. In another series, defective vitamin B<sub>12</sub> absorption was found in 7 of 22 patients with iron deficiency complicated by histamine-fast achlorhydria.<sup>168</sup> These reports probably indicate the severity of the gastric damage in iron deficiency, rather than coincidental pernicious anemia.

Antibodies to gastric parietal cells (Chapter 15, page 606) are found in about one third of patients with iron deficiency.<sup>178,191</sup> Although the mechanism of production of these antibodies is not understood, they are more

likely to be a manifestation of gastritis than the cause.<sup>143</sup>

### *Ozena*

Ozena is a disease of unknown cause characterized by chronic atrophy of the nasal mucosa associated with a foul-smelling discharge. Although uncommon in the United States, ozena occurs relatively frequently in southeastern Europe. There, an association between ozena and iron deficiency was observed.<sup>165</sup> About three fourths of 136 patients with ozena had hypochromic anemia or hypoferrremia or both. Furthermore, improvement or complete relief was observed following iron therapy. On the basis of these observations as well as epidemiologic information,

it was concluded that ozena is a manifestation of chronic iron deficiency. On the other hand, ozena is rare in Norway even though iron deficiency is common.<sup>164</sup> There, only nine of 24,176 patients visiting an ear, nose, and throat clinic were found to have ozena. None of the nine had anemia, hypochromia, or hypoferrremia, and eight had adequate iron stores in the bone marrow. Others have reported failure of iron therapy in ozena.<sup>184</sup> It therefore appears that if iron deficiency plays any role at all in the cause of ozena, it is but one factor in a multifactorial disease.

### *Pica*

Pica has been previously alluded to as a possible cause of iron deficiency (page 641).

Fig. 17-9. Esophageal web (arrow) in Plummer-Vinson syndrome

It may also be a striking manifestation of the disease. Hippocrates wrote that a "craving to eat earth" was associated with "corruption of the blood."<sup>1</sup> "Perversion of the appetite" was a prominent symptom in chlorosis.<sup>23</sup>

Pagophagia, defined as the purposeful eating of at least one tray of ice daily for two months, was reported in 25 adult patients with iron deficiency.<sup>60</sup> The ingestion of ice averaged nearly 2 kg per day, and some patients ate an astounding 4 to 9 kg per day. This dramatic symptom was relieved within 1 to 14 days after iron was administered. Another study found that pagophagia was a symptom of iron deficiency in 23 of 38 consecutive adult patients; iron therapy was curative.<sup>186</sup>

Other forms of pica occur particularly in children and may also respond to iron therapy.<sup>103</sup>

### The Spleen

The spleen is enlarged in about 10% of patients.<sup>27,60</sup> The degree of enlargement is slight; usually only the tip is felt. There are no specific pathologic changes in the organ, and the pathogenesis of the enlargement is unknown.

### Genitourinary System

Disturbances in menstruation are frequent, but it is sometimes difficult to be certain whether they are the cause or the result of deficiency. Several investigators have reported that menorrhagia was relieved by iron therapy.<sup>27,171,188</sup> However, in a study in which <sup>51</sup>Cr-labeling was used to measure menstrual blood loss, the flow did not decrease and often even became heavier after therapy.<sup>175</sup>

### Neuromuscular System

There may be neuralgic pains, vasomotor disturbances, or numbness and tingling. The last-mentioned complaints have been observed in 15 to 30% of patients with chronic hypochromic anemia.<sup>27</sup> More serious symp-

oms, such as disturbances of gait and objective neurologic findings, are unusual.<sup>187</sup>

Rarely, iron deficiency may lead to increased intracranial pressure, papilledema, and the clinical picture of pseudotumor cerebri.<sup>167</sup> About 44 such cases have been reported, and in 29 of these the information provided was adequate to exclude occult intracranial lesions and to establish the fact that the condition was corrected after iron therapy. The pathogenesis is unknown, but it was suggested that severe anemia and reduced tissue iron enzymes might lead to cerebral anoxia and edema, as occurs in carbon monoxide intoxication.<sup>167</sup>

### Skeletal System

In children with iron-deficiency anemia of long standing, there may be changes in the skull similar to those found in association with thalassemia or chronic hemolytic anemia.<sup>161,168,180</sup> The diploic spaces may be widened and the outer tables thinned, at times with vertical striations producing a hair-on-end appearance. In addition, there may be abnormalities of the long bones, especially the metacarpals and phalanges, with expansion of the medulla and thinning of the cortices.<sup>180</sup> The changes are thought to result from expansion of the erythroid marrow during the period of bone growth and development.

## Laboratory Findings

### The Blood

#### Erythrocytes

The degree of anemia depends on the presenting circumstances. If discovered when the patient is evaluated for an underlying or unrelated disease, the anemia may be mild. If symptoms of anemia are the presenting complaint, the blood hemoglobin is usually 8 g/dl or lower. In 371 English patients, the mean hemoglobin was 7.6 g/dl, with values of less than 4 g/dl in eight, and greater than

11 g/dl in five.<sup>60</sup> In 115 patients in the United States the VPRC ranged from 0.10 to 0.40 l/l, with a mean of 0.30 l/l (hemoglobin 8.4 g/dl).<sup>2</sup> A similar range of values has been reported by others, in both adults<sup>219</sup> and children.<sup>220</sup> Because of the hypochromia, the hemoglobin is usually reduced to a greater degree than the VPRC.

The mean corpuscular volume (MCV), mean corpuscular hemoglobin (MCH), and mean corpuscular hemoglobin concentration (MCHC) are all reduced in the usual patient. The average MCV is 74 fl (range, 53 to 93), MCHC 28 g/dl (22 to 31), and MCH 20 pg (14 to 29).<sup>2,219</sup> Similar values were found in infants.<sup>220</sup> The degree of change in the red cell indices is related partly to the duration<sup>8</sup> and partly to the severity of the anemia. In mild iron deficiency of short duration the indices may be normal.<sup>204</sup>

Both the percentage and the absolute number of reticulocytes tend to be normal or slightly increased,<sup>2,219</sup> but, rarely, they may be reduced. In experimentally induced iron deficiency in certain animal species, including rats and pigs, a pronounced reticulocytosis is seen.<sup>207,219</sup>

The chief finding on blood smear is the

poverty of hemoglobin in the individual red corpuscles, as indicated by an exaggeration of their central pallor (Fig. 17-10). The more severe the anemia, the greater the degree of this change and the more numerous the corpuscles affected. In extreme grades of hypochromic anemia, most of the red corpuscles are mere rings. Tiny microcytes and a moderate number of poikilocytes, particularly tailed and elongated elliptical forms, also are found. In almost all instances, however, a variable number of well-filled red corpuscles are present and some macrocytes, often polychromatophilic, can be distinguished. These may represent cells made during occasional periods of increased iron availability, for example, after a meal rich in iron. The number of such cells is increased as iron is made available. The diagnosis of iron-deficiency anemia from blood smear alone may be difficult.<sup>212</sup>

The fragility of the red corpuscles may be within the normal range, but often there is increased resistance to destruction in hypotonic salt solutions, a pale layer of unbroken cells remaining in tubes of salt concentration as low as 0.21 g/dl. Extreme grades of corpuscular resistance, however, such as are

Fig. 17-10. Blood smear from a patient with hypochromic, microcytic anemia due to iron deficiency. Red corpuscles from normal blood are shown, for comparison, on each side (Wright's stain,  $\times 900$ )

found in thalassemia (Chapter 26) are unusual. The abnormal osmotic fragility returns to normal following adequate therapy.<sup>221</sup>

### *Leukocytes and Platelets*

The leukocytes are usually normal in number, but there may be slight absolute granulocytopenia in long-standing cases.<sup>225</sup> A few hypersegmented neutrophils may be found,<sup>203</sup> but it is sometimes difficult to exclude the possibility that folate deficiency in the recent past is responsible for the finding.<sup>216</sup> A fresh hemorrhage of large volume may cause slight neutrophilic leukocytosis, with even the appearance of an occasional myelocyte. In hookworm anemia, eosinophilia is common.<sup>121</sup>

The platelet count usually is increased to about twice the normal level, and values return to normal after therapy.<sup>215,223</sup> It has been claimed that this thrombocytosis reflects continuing blood loss rather than iron deficiency.<sup>210</sup> However, dietary iron deficiency in rats also is accompanied by thrombocytosis.<sup>223</sup> In some patients with iron-deficiency anemia that is severe or of long standing, mild thrombocytopenia may be observed, possibly because of complicating factors such as folate deficiency or splenic sequestration.<sup>210,215</sup>

### *Bone Marrow*

The bone marrow is characterized by erythroid hyperplasia of a variable, but generally mild to moderate, degree. Of the nucleated cells in marrow aspirates from iron-deficient patients,  $25 \pm 9.8\%$  were erythroblasts as compared with  $16.9 \pm 2.7\%$  in normal subjects.<sup>206</sup> Furthermore, cellularity of the marrow, as judged from sections of marrow fragments, was moderately increased in the deficient patient. There was no good correlation between any of these changes and the degree of anemia. Striking nuclear distortions, resembling those found in dyserythropoietic anemias (Chap. 19), may sometimes be observed in the marrow.<sup>216a</sup> Karyorrhexis and nuclear budding are particularly common, but

multinuclearity, nuclear fragmentation, and even intranuclear bridging may be observed. When therapy is given, erythroid hyperplasia initially increases, but as the blood is restored to normal the cellularity of the marrow likewise becomes normal.

The individual normoblasts appear small, and may have scanty cytoplasm, often with irregular, ragged borders. Findings in the marrow after staining for iron are described below.

### *Kinetic Studies*

Studies employing the  $DF^{52}P$  or Ashby methods demonstrate that the red cell survival is somewhat shortened<sup>209,217</sup> (Table 17-8). Only when the change is severe can it be detected with the  $^{51}Cr$  method.<sup>209,218</sup> That the shortened survival results from an intracorporeal defect has been demonstrated by cross-transfusion studies.<sup>209,217</sup> Furthermore there is excellent correlation between the degree to which red cell survival is shortened and the proportion of morphologically abnormal cells on blood smear.<sup>209</sup> The principal site of destruction appears to be the spleen.<sup>218</sup> One study indicated that administration of prednisone prolongs red cell survival in iron deficiency, whereas the effect of iron on survival is delayed until the abnormal cells disappear.<sup>211</sup>

Ferroketic studies have been puzzling because they seem to show that, despite a low plasma iron, iron clearance is so rapid that a normal amount of iron is delivered to marrow, where it is utilized more efficiently than normal, resulting in an apparent net increase in hemoglobin production as represented by the erythrocyte iron turnover rate (EIT) (Table 17-8). These data are clarified by the observation that there was a significant component of "ineffective erythropoiesis" in iron-deficient rats, as demonstrated by marked augmentation of the "early-labeled" bilirubin fraction (Chapter 5).<sup>222</sup> This would suggest that a proportion of cells in iron deficiency are so defective that they are rapidly destroyed, and that the iron they contain is quickly reutilized. The iron traveling

† Values are means

through such a shunt pathway would account for the ferrokinetic peculiarities.

### Iron Metabolism

In sera of adults with iron-deficiency anemia, iron concentration is reduced to an average of 28 µg/dl (range 10 to 61).<sup>2</sup> The total iron-binding capacity (TIBC) often is increased, but it may be normal or even decreased (Fig. 16-3). In one study, the average value was 346 µg/dl, range 170 to 460.<sup>2</sup> The patients with reduced TIBC values tended to have hypoalbuminemia as well. Saturation of transferrin is always reduced to less than 16% and averages 7%. Values for serum iron, TIBC, and transferrin saturation are similar in iron-deficient children, except that the increase in TIBC is more consistent.<sup>220</sup>

Reticuloendothelial iron stores are absent or severely reduced in marrow or liver. Less than 10% (average 2.5%) of the marrow normoblasts are sideroblasts.<sup>2</sup>

Comparison of these abnormalities with those in other hypochromic anemias is discussed in Chapter 16.

### Iron Enzymes

In addition to being a component of hemoglobin, iron forms a part of a number of important tissue enzymes, including cytochrome c, cytochrome oxidase, catalase,

myoglobin, succinic dehydrogenase, aconitase, and possibly glutamate formiminotransferase.<sup>203,205,215,224</sup> In experimentally induced iron deficiency in animals, the activity of many of these enzymes becomes reduced and can be restored by iron treatment. Various tissues, including brain, heart, liver, kidney, and muscle, may be affected.

Studies in man obviously are more difficult than in experimental animals because tissues are not so readily available. However, it has been demonstrated that catalase is decreased in erythrocytes of human subjects with iron deficiency.<sup>202</sup> Also, cytochrome oxidase activity is reduced in buccal epithelium<sup>9</sup> and in intestinal epithelium.<sup>203</sup> In the latter, when iron is given, regeneration of cytochrome oxidase begins in newly formed cells at the base of the intestinal villus, and over a three- to four-day period these cells gradually replace the older, deficient cells.<sup>203</sup>

The pathophysiologic importance of changes in tissue enzymes remains uncertain. It has been suggested that the abnormalities may partially account for the symptom of fatigue.<sup>3</sup> The significance of fatigue as a symptom of iron deficiency was discussed earlier (page 650). Another suggestion is that the epithelial manifestations of iron deficiency are related to impaired activities of these enzymes. However, no correlation could be found between buccal cytochrome oxidase activity and atrophic mucosa.<sup>9</sup>

## Lactate Acidosis

Lactate acidosis was observed in a single patient with very severe iron-deficiency anemia (blood hemoglobin 1.5 g/dl).<sup>214</sup>

## Management

### Measures Directed at the Cause of the Anemia

Every effort must be made to define the etiologic factor. This should be possible in about 80 to 85% of patients.<sup>60</sup> In the remainder, it is possible that the underlying disease is in remission; therefore, continued observation for new clues as to its nature is warranted. Once the etiologic diagnosis is made, appropriate treatment becomes possible. Therapy may be as simple as discontinuing salicylate ingestion or it may require complex decisions between medical and surgical approaches to bleeding gastrointestinal lesions. It is in the area of primary diagnosis and therapy that the difficult and challenging problems in management of iron deficiency lie. By comparison, repletion of total body iron stores is relatively simple.

### Measures Designed to Replenish Total Body Iron

Iron is highly effective in treating iron deficiency. *It has no other legitimate therapeutic use*, in particular it exerts no effect in any of the numerous anemias which are not due to iron deficiency. The practice of giving

iron indiscriminately in undiagnosed anemia cannot be deplored too emphatically. It will certainly do no good, may do harm, and may delay institution of other, more suitable, therapeutic measures.

Iron can be administered orally, intramuscularly, or intravenously. Of these, the oral route is by far the safest and least expensive. Iron-deficient patients who cannot tolerate oral therapy or who fail to respond to it when properly given are most unusual.

### Oral Iron Therapy

**RECOMMENDED PREPARATIONS AND ADMINISTRATION.** The standard preparation for oral use is ferrous sulfate. It is effective, well-tolerated, and inexpensive. If equivalent amounts of elemental iron are given, two other iron salts are equally satisfactory, have about the same incidence of side effects, and cost only slightly more than ferrous sulfate. These are ferrous gluconate and ferrous fumarate (Table 17-9).

The dose is best calculated in terms of elemental iron. For adults, the optimal response occurs when about 200 mg of elemental iron are given each day. Three ferrous sulfate tablets or 5 teaspoons of ferrous sulfate elixir provide this daily dose. To achieve similar doses with ferrous gluconate, 5 tablets per day are required. Ferrous fumarate can be given two or three times a day, depending on the tablet size (Table 17-9).

Iron is absorbed more completely when the stomach is empty; when taken after or with

Table 17-9. Standard Therapeutic Oral Iron Preparations

Preparation	Size	Iron Content	Usual Adult Daily Dose	Approximate Cost per Month
<b>Ferrous sulfate</b>				
Tablets (hydrated)	300 mg	60 mg	3 tablets	\$1.50
Tablets (exsiccated)	200 mg	60 mg	3 tablets	\$1.50
Syrup and elixirs	40 mg/ml	8 mg/ml	25 ml (5 tsp)	\$4.00
Pediatric drops	125 mg/ml	25 mg/ml	—	—
<b>Ferrous gluconate</b>				
	300 mg	37 mg	5 tablets	\$3.00
<b>Ferrous fumarate</b>				
	200 mg	67 mg	3 tablets	\$2.50
	300 mg	100 mg	2 tablets	

a meal, absorption was found to decrease by 40 to 50%.<sup>235</sup> However, gastrointestinal irritation is common when the stomach is empty; consequently it is usually better to advise that the tablet be taken immediately after or even with a meal; the gain in patient acceptance may be more important than the reduced absorption of iron. The daily dose, furthermore, should be divided roughly in accordance with the size of the meal. Even two tablets may be readily tolerated after a large meal, whereas one may cause discomfort if the stomach is empty.

As Blaud recognized more than a century ago, *tolerance for iron salts usually is improved by giving a small dose at first and increasing the amount in the course of several days to the full dose of 3 tablets. Without such a gradual increase in dosage, gastrointestinal side effects are more common.*

For children, 1.5 to 2.0 mg elemental iron per kg body weight three times a day are effective. Palatable elixirs and syrups are the most satisfactory pediatric preparations. Children usually tolerate this form of therapy on an empty stomach.

Studies of the absorption of medicinal iron in deficient subjects are difficult because many patients continue to bleed and therefore lose iron. One study circumvented this problem by using eight healthy male volunteers in whom iron-deficiency anemia (Hb 9.2 to 11.4, MCHC 28.3 to 31.7) was induced by phlebotomy.<sup>244</sup> At therapeutic doses of ferrous sulfate (222 mg elemental iron per day), 13.5% (range 10.6 to 18.7%) was absorbed during the first 20 days of therapy. It was calculated that 605 mg of iron were absorbed during this period. As hemoglobin regeneration occurred, absorption decreased; in the period 21 to 30 days after therapy was begun, the average value was 5.1% (2.3 to 6.0). Since the number of individuals studied was small, these figures can serve as only a rough guide to expected absorption in others. Individual variations are great and absorption may be vastly different at different degrees of anemia and in the presence of complicating illnesses.

The 200-mg daily dose will produce a maximum rate of hemoglobin regeneration.

It is not necessarily true, however, that the maximum rate is the only legitimate therapeutic goal. If the underlying disease has been corrected and if the anemia is mild to moderate, a slower rate of response may be acceptable. Thus, if such patients cannot tolerate 200 mg a day of elemental iron as ferrous sulfate, it is reasonable to reduce the dose to about 100 mg a day. A convenient way to accomplish this is with ferrous gluconate, since 3 tablets a day will provide 110 mg iron. Because less iron is given, tolerance is improved. In this circumstance, speed of response is exchanged for patient acceptance. Therapy will probably be prolonged, but this may be no great disadvantage to the selected patients.

Regardless of the form of oral therapy used, it is important to continue treatment for at least six months after the anemia has been relieved. If this is not done, relapse is common. The continued therapy allows for repletion of iron stores.

**SIDE EFFECTS.** Some patients given iron by mouth complain of gastrointestinal symptoms, including heartburn, nausea, abdominal cramps, and diarrhea. In many instances, both the frequency and severity of the symptoms have been greatly exaggerated. Functional gastrointestinal symptoms are common in the absence of medication; furthermore, they are greatly influenced by suggestion.

Many studies of gastrointestinal intolerance to iron have not included adequate controls. In one excellent, double blind study, ferrous sulfate, ferrous gluconate, ferrous fumarate, and placebo were administered in identically appearing tablets.<sup>243</sup> The elemental iron dose was 222 mg per day. The incidence of gastrointestinal side effects was 13% in subjects taking placebo tablets and 25% in those taking iron. No significant differences were found among the three iron salts. Thus, about 12% had symptoms that could reasonably be ascribed to iron.

It is probable that side effects are related to dose. In another controlled study, iron was given in a dose of 105 mg/day.<sup>247</sup> About 20% of the members of both the iron and the

placebo groups complained of side effects. Thus, at this dose level there were no side effects which could be attributed to iron. In an uncontrolled study limited to young men, 150 mg elemental iron were given as ferrous sulfate per day. No gastrointestinal symptoms were experienced.<sup>236</sup> These studies suggest that patients intolerant of full therapeutic doses may be able to take smaller ones, especially if appropriate psychologic tactics are employed.

**OTHER PREPARATIONS.** A great variety of compounds containing iron have been promoted from time to time with claims of greater effectiveness, greater tolerance, and less toxicity than ferrous sulfate, ferrous gluconate, or ferrous fumarate. In general, these compounds are considerably more expensive than ferrous sulfate. Often, allegations of significant therapeutic superiority or reduced toxicity have not been substantiated.<sup>34,238</sup>

If given in sufficient quantities both ascorbic acid and succinic acid increase absorption of ferrous iron. In the case of ascorbate, at least 200 mg are necessary for each 30 mg of iron, and the increase in absorption at that level is about 30%.<sup>235</sup> However, ascorbate also increases the side effects of iron therapy<sup>213</sup>; thus, it appears that an increase in the dose of iron would achieve the same result at lower cost. Furthermore, many of the available iron and ascorbate preparations contain only trifling amounts of ascorbate.

Unlike ascorbic acid, *succinic acid* promotes iron absorption without increasing the side effects.<sup>243,244</sup> Again, relatively large amounts are required approximately 185 mg succinic acid per 37 mg of iron. In this ratio and with an elemental iron dose of 222 mg per day, the observed absorption in iron deficiency was 21% during the first 20 days of treatment as compared to 12.5% without succinate.<sup>244</sup> It was calculated that the total amount of iron absorbed in 20 days was 940 mg with succinate and 608 without. Iron-succinic acid preparations are not available in the United States, but ferrous succinate is in use in Great Britain. There, the cost is about eight times that of ferrous sulfate.<sup>144</sup> In most

cases, it is doubtful that the increment in absorption justifies the extra cost.

Enteric coated preparations are designed to reduce side effects by retarding dissolution of the iron. However, this effect may markedly decrease absorption, especially in achlorhydric individuals, whose gastric juice cannot dissolve the coating.<sup>31</sup> Sustained release preparations also reduce side effects by retarding dissolution, but in so doing the most actively absorbing regions of the intestine are bypassed; hence, absorption is reduced.<sup>234,237,251</sup> Certain iron compounds are poorly soluble and poorly absorbed, including ferric salts, ferrous carbonate, and ferrous sulfate when mixed with aluminum and magnesium hydroxides. Addition of copper, cobalt, molybdenum, and a variety of other minerals as well as vitamins and "hematinics" confers no therapeutic advantage and adds considerable expense.

**FAILURE OF ORAL IRON THERAPY.** It is not uncommon to encounter patients who are said to have iron-deficiency anemia that is unresponsive to oral therapy. Often such individuals are referred to the hematologist with the suggestion that iron absorption is defective, but that hypothesis usually turns out to be incorrect. In approximate order of importance, the following possible explanations for failure to respond to iron given orally should be considered: (1) incorrect diagnosis; (2) complicating illness; (3) failure of patient to take prescribed medication; (4) inadequate prescription (dose or form); (5) continuing iron loss in excess of intake; and (6) malabsorption of iron.

Of paramount importance is a review of the data upon which the diagnosis of iron deficiency anemia was based along with judicious repetition of any laboratory procedures that might have yielded erroneous information. At times, even though iron deficiency is present, a coexisting cause for anemia may impair response. Common examples are iron deficiency as a complication of the anemia of chronic disorders in rheumatoid arthritis, and so-called "dimorphic anemia" in which iron deficiency and pernicious anemia coexist.

Even apparently intelligent and cooperative patients may fail to take medications as prescribed.<sup>250</sup> As a check on this possibility, it is sometimes wise to ask the patient to bring the medication bottle to the physician for a "pill count." As has been mentioned, some available iron preparations contain inadequate amounts of iron, or are poorly absorbed because of such factors as enteric coatings or reduced solubility. In these instances, simply prescribing ferrous sulfate can bring about response.<sup>251</sup> In occasional patients, blood loss is so great that oral iron therapy cannot keep up with it. If this situation is not correctable, as may be the case, for example, in hereditary hemorrhagic telangiectasia, parenteral therapy must be given. Finally, a rare patient may be unable to absorb iron, although even patients with sprue or total gastrectomy usually are able to absorb adequate amounts of ferrous sulfate.

### Parenteral Iron Therapy

Parenteral iron therapy is as effective but somewhat more dangerous and considerably more expensive than oral therapy. Nevertheless, there are certain clinical situations in which failure of oral therapy is to be expected. It should be emphasized that a history of failure to respond to oral iron is not, by itself, an indication for parenteral therapy. The reasons for failure must be analyzed as outlined above.

Parenteral iron therapy is indicated when the patient (1) is unable to tolerate iron compounds given orally; (2) repeatedly fails to heed instructions or is incapable of accepting or following them; (3) loses iron (blood) at a rate too rapid to be compensated for by the oral intake (eg, hereditary hemorrhagic telangiectasia); (4) has a disorder of the gastrointestinal tract, such as ulcerative colitis, in which symptoms may be aggravated by iron therapy; or (5) is unable to absorb iron from the gastrointestinal tract.

**PREPARATIONS AND ADMINISTRATION.** Available preparations include iron-dextran complex (Imferon) and iron sorbitex (Jecto-

fer), both of which contain 50 mg of iron per ml of solution. The total dose of parenteral agents may be calculated from the amount of iron needed to restore the hemoglobin deficit plus an additional amount to replenish stores. One formula that allows for both is as follows<sup>144</sup>:

$$\begin{aligned} \text{iron to be injected (mg)} \\ = (15 - \text{patient's Hb}) \times \text{body weight} \times 3 \\ \quad \quad \quad \text{(g/dl)} \quad \quad \quad \text{(kg)} \end{aligned}$$

The most extensively used preparation is iron-dextran complex which can be given intramuscularly or intravenously. The intramuscular injections should always be made deep into the upper outer quadrant of the buttock, and the skin should be laterally displaced prior to injection (Z-track technique) to prevent staining of the skin. A test dose of 0.5 ml should be given initially to test for hypersensitivity. Thereafter, usually no more than 2.5 ml are given per injection, but both buttocks may be injected daily for a total of 5 ml (250 mg) per day. Approximately 65% is absorbed from the injection site in 72 hours.<sup>252</sup> An average of about 25% (range 11 to 52%) remains at the injection site for at least four weeks and may be essentially unavailable.<sup>256</sup>

Iron-dextran complex can also be given intravenously. The special advantage of this route is that larger doses can be given in a single injection and the discomfort and inconvenience of repeated intramuscular injections thereby avoided. Since the intravenous route may be more dangerous, however, its use should be reserved for special situations in which rapid replenishment or repeated large doses are needed, as in continuous blood loss. Two methods have been used.<sup>254</sup> After testing for hypersensitivity, 5 to 10 ml of undiluted iron-dextran complex may be administered over a period of five minutes. Alternatively, the entire dose, as calculated by the formula given above, may be given diluted in a ratio of 5 ml iron-dextran complex to 100 ml saline solution. This method, sometimes called total dose infusion or TDI, has not yet gained approval of the U.S. Food and Drug Administration,

but has been used extensively in Great Britain and continental Europe. Glucose solutions may also be used as the diluent, but the incidence of phlebitis is greater than when saline solution is employed. The initial flow rate should be 20 drops/min for five minutes; then, if no side effects are observed, the rate may be increased to 40 to 60 drops/min.

*Iron sorbitex* (iron sorbitol-citric acid complex, Jectofer)<sup>239 245</sup> is a low molecular-weight (5000) preparation for intramuscular use. It is much more rapidly absorbed from the injection site than is iron-dextran complex; less than 15% remains after 24 hours. About 25% is excreted into the urine, and the calculated total dose should take this loss into account. The dose should not exceed 1.5 mg/kg or a total of 100 mg per day.

**SIDE EFFECTS.** Staining of the skin may follow intramuscular injection of iron-dextran complex. There may be pain at the injection site, approximately equivalent to that produced by a penicillin injection. Regional lymph nodes may become tender for several weeks. Phlebitis occurs after intravenous administration in as many as 25% of the injections when dextrose solution is used as diluent, but is less frequent when saline solution is used. With both the intravenous and intramuscular routes, various systemic reactions occur, including headache, flushing, febrile reactions, arthritis, urticaria, nausea, and bronchospasm. However, the overall incidence of such side effects (excluding fever and arthralgia) in 2400 patients given iron-dextran complex intravenously was only 1 to 2%.<sup>254</sup> Furthermore, most reactions were mild and transient. However, anaphylaxis has been observed following both intramuscular and intravenous injections and may be fatal.<sup>232</sup> The clinician should be prepared for the possibility of anaphylaxis and have epinephrine, oxygen, and facilities for resuscitation on hand for the initial injections.

In rats, iron-dextran complex in very large intramuscular doses was found to induce sarcomas at the injection site.<sup>241</sup> This observation led to the temporary withdrawal of the product between 1960 and 1963. There has

been no evidence of carcinogenicity in man at normal doses.

Iron sorbitex may discolor skin, but less frequently than does iron-dextran complex. A small proportion of the iron in this preparation is ionizable, and if the iron-binding capacity is exceeded, there may be marked systemic reactions, including vasomotor collapse and shock. Many patients complain of a metallic taste which may persist more than a day. At the 100-mg dose, systemic reactions occur in about 5% of patients, and the incidence is higher at greater doses.

### *Response to Therapy*

When specific iron therapy is given, there may be rapid subjective improvement with disappearance or marked diminution of fatigue, lassitude, and other nonspecific symptoms. This response may occur before any evidence of hemoglobin regeneration is observed. One variety of pica, pagophagia or ice-eating, was relieved within one week of therapy.<sup>64</sup>

The earliest hematologic evidence of response to treatment is an increase in the percentage of reticulocytes. The increase generally is slower to appear and not so marked as may be observed following vitamin B<sub>12</sub> therapy of pernicious anemia (page 594). The reticulocytes attain a maximum value on the fifth to the tenth day after institution of therapy, and thereafter gradually return to normal. The maximum value usually ranges from 5 to 10% and is inversely related to the level of hemoglobin.<sup>232</sup> With only slight to moderate degrees of anemia, a pronounced reticulocyte response cannot be expected.

The rate of change in blood hemoglobin levels induced by iron therapy also varies with the degree of anemia (Fig. 17-11). The hemoglobin increases more rapidly at low levels than at high, and it takes about two months to reach normal values, regardless of starting levels. Two simple guidelines that can be used to assess the adequacy of response to therapy are: (1) the hemoglobin should increase to a value half-way between starting level and normal in an average of 18

Fig 17-11. The change in blood hemoglobin with time after optimal iron therapy. The more severe the anemia, the more rapid the response. Usually normal values are reached by eight weeks regardless of the starting levels. (From the data of Swan and Jowett<sup>233</sup>)

days; and (2) at three weeks, the hemoglobin should have risen  $59 \pm 17\%$  (mean  $\pm$  S.D.) toward normal.<sup>253</sup> The last observation emphasizes the potential variability of response; to include 95% of normal values (mean  $\pm$  2

S.D.) the increase at three weeks would range from 25 to 93% of the difference between the initial value and normal.

The blood hemoglobin is the most accurate representation of the degree of anemia in iron deficiency. During the response to therapy, the red cell count may temporarily increase to values above normal, but the hemoglobin value lags behind (Fig. 17-12). The red cell indices may remain abnormal for some time after the normal hemoglobin level has been restored (Fig. 17-12).

Of the epithelial lesions in iron deficiency, those affecting the tongue and nails are the most responsive to treatment. After one to two weeks, small regenerating filiform papillae are observed, and this change is also seen on biopsy.<sup>163</sup> By three months the tongue has usually returned to normal, but in patients with severe cases, some atrophy may persist. Koilonychia usually disappears in three to six months, the concavity moving toward the end of the nail as the nail grows. Gastritis and the associated defects in gastric secretion often do not respond to therapy, especially in older adults.<sup>171</sup> In patients less than 30 years of age, gastric acid secretion and normal

Fig 17-12. Blood changes in a patient with iron deficiency. All values are shown in proportion to the normal for the individual. Note the rapid increase in hemoglobin (Hb) following commencement of iron therapy and then the more gradual rise, the increase in the erythrocyte count (RBC) to values above normal, and the eventual restoration of all values to normal, including those for mean corpuscular hemoglobin concentration (MCC). (From Wintrobe and Beebe,<sup>27</sup> courtesy of the authors and Williams & Wilkins)

epithelial architecture may be restored.<sup>178</sup> Least responsive is sideropenic dysphagia which almost never responds to iron therapy unless dilatation of the upper esophagus also is performed.<sup>141</sup>

In about one third of patients who respond to iron treatment, *relapse* is experienced later, partly because of failure to take medication long enough and partly because of recurrent disease.<sup>60</sup>

### Acute Iron Intoxication

The accidental ingestion of iron compounds by children who have mistaken the tablets for candy is a common pediatric problem. At one time the mortality was as high as 50%. The children who died had swallowed 3 to 10 g or more. Symptoms have been classified in four stages.<sup>246</sup> In stage one, gastrointestinal symptoms predominate (vomiting, diarrhea, melena). Shock may follow, then dyspnea, lethargy, and coma. These events take place in the first six hours following ingestion. In the second stage, lasting from 6 to 24 hours after ingestion, transient improvement occurs and may continue to recovery. In stage three, metabolic acidosis is present. Death may take place 12 to 48 hours after ingestion.

These ill effects are the consequence of the local irritative action of the iron, with mucosal ulceration and bleeding. Capillary dilatation and diapedesis of red cells may occur. Many factors cause the shock, including the absorption of iron in amounts far above the binding capacity of the plasma. Serum iron values as high as 3000 µg/dl have been observed. The cause of the metabolic acidosis is uncertain.<sup>246</sup> Late coma is the result of hypoxia, metabolic disturbances, and hepatic damage.

The introduction of desferrioxamine<sup>231</sup> as a therapeutic agent has greatly modified the outlook.<sup>246,255</sup> This weak base, which has a high specific affinity for iron, can be given orally and intravenously. The molecular complex is small and is excreted quickly by the kidneys. Toxicity is manifested mainly by hypotension, skin rashes, and, when the drug

is ingested in large doses, intestinal irritation.

Aspiration and lavage with 1% sodium bicarbonate should be carried out in any patient who has taken, or even if only suspected of having taken, an overdose of iron salts.<sup>246</sup> Desferrioxamine, 3 g dissolved in 50 ml of distilled water, should be instilled via the nasogastric tube. An intravenous infusion of 1 liter of 5% dextrose in water containing 100 mg desferrioxamine is begun, after drawing blood for measurement of serum iron and total iron-binding capacity. To avoid hypotensive reactions, the rate of infusion should not exceed 15 mg per kg of body weight per hour. The total amount given intravenously will depend on the clinical response. In addition, general supportive measures for shock and acidosis are employed.

If desferrioxamine is not available, calcium disodium EDTA, 80 mg per kg body weight per 24 hours, may be used.<sup>245</sup>

of chronic disorders and increased in sideroblastic anemia.

### Anemia of Chronic Disorders

A mild to moderate anemia frequently accompanies infectious, inflammatory, or neoplastic diseases that persist for more than one or two months (Table 18-1).<sup>8,9,10</sup> Since there are so many such diseases, this type of anemia is very common, perhaps second only to iron-deficiency anemia in overall incidence. The associated biochemical and kinetic alterations form a characteristic pattern, of which the most distinctive feature is the occurrence of hypoferrremia despite abundant quantities of iron in the reticuloendothelial storage depots. The anemia of chronic disorders is defined by the presence of this unique combination of findings.<sup>8,9</sup>

The designation, "anemia of chronic disorders," is far from ideal, but proposed alternatives are even less satisfactory. As defined above, the term is not intended to be used in relation to anemia produced by other mechanisms, such as blood loss, overt hemolysis, or myelophthisis, any one of which may also occur in patients with chronic disorders. Nor is the term meant to refer to anemia in other, equally "chronic" disorders, such as certain renal, hepatic, and endocrine diseases,

**B**OTH the anemia of chronic disorders and the sideroblastic anemias are associated with signs of disturbed iron metabolism, and, in both, hypochromic erythrocytes may be observed. There is rarely any difficulty, however, in distinguishing the two conditions, since, among many other differences, the plasma iron is decreased in the anemia

**Table 18-1. Conditions Associated with the Anemia of Chronic Disorders**

c	Lymphosarcoma
d	Leukemia
e	Multiple myeloma
4	Idiopathic <sup>26</sup>

because, in these, the anemia is not necessarily accompanied by the above-described disturbance in iron metabolism. More descriptive, but infrequently used designations include "hypoferremic anemia with reticulo-endothelial siderosis" and "thesauric, hypoferremic anemia."<sup>9</sup>

### Symptomatology

Since this type of anemia occurs in association with so many diseases, the clinical manifestations necessarily vary widely. Usually the signs and symptoms of the underlying disorder overshadow those of the anemia, but, in occasional patients, reduction of the hemoglobin level provides the first evidence of the existence of the primary condition.

### Characteristics of the Anemia

#### Development and Severity

Anemia develops during the first one to two months of illness and thereafter does not

progress (Fig. 18-1).<sup>8</sup> Almost never severely depressed, the VPRC usually is maintained between 0.30 and 0.40 l/l (Fig. 18-2).<sup>8,10</sup> The degree of change may be so modest that the value remains within the low normal range.

Total blood volume was found to be reduced below normal in some patients with anemia due to infection,<sup>10</sup> whereas in others an increase in plasma volume was noted. Such observations imply that the hemoglobin concentration or VPRC may not always reflect the true degree of alteration in the total circulating red cell mass. In most circumstances, however, these measures of concentration are satisfactory indicators of the degree of anemia.

There is a rough correlation between the degree of anemia and the severity of the underlying disease. For example, infections which are accompanied by pronounced fever, chills, and suppuration are associated with more severe anemia than are those with fewer systemic manifestations.<sup>8</sup> There is some evidence that the greater the number of organisms in a wound, the more severe the anemia. Correlation between the severity of the anemia and the activity of rheumatoid arthritis, as judged by fever, severity of joint swelling and inflammation, and the sedimentation

**Fig 18-1** The development of anemia, as measured by the volume of packed red cells (VPRC), in 50 patients with chronic infections (From Cartwright,<sup>8</sup> courtesy of the author and Henry M. Stratton, Inc.)

Fig 18-2. Degree and type of anemia as indicated by the volume of packed red cells, the mean corpuscular volume and the mean corpuscular hemoglobin concentration in 50 patients with anemia due to infection (From Cartwright and Wintrobe<sup>10</sup> courtesy of the authors and Year Book Medical Publishers, Inc.)

rate, also has been observed.<sup>31</sup> In patients with malignant disease, anemia is more severe when there are widespread metastases than when the disease is localized; however, the development of anemia does not require invasion of the bone marrow.<sup>30,42</sup> The anemia of malignant disease may also take other forms (see sideroblastic anemia, page 685, and myelophthisic anemia, Chapter 57).

### Morphologic Features

The anemia usually is normocytic and normochromic (Fig. 18-2). However, hypochromia (MCHC 26 to 32 g/dl) has been observed in 23 to 50% of patients with chronic infection, 50 to 100% of patients with rheumatoid arthritis, and 44 to 64% of patients with cancer.<sup>8</sup> Hypochromia may be observed even though the VPRC remains within normal limits.<sup>36</sup> Microcytosis is encountered less often than hypochromia and, when present, is usually not as great as is commonly found in iron-deficiency anemia. Values for MCV below 72 fl are rare.<sup>8</sup>

Anisocytosis of moderate degree may be detected, but poikilocytosis is slight. As a rule, few other changes in the red cells are observed. Evidence of attempted regeneration, such as polychromatophilia or the presence of nucleated red cells in the circulation, is conspicuous by its absence. Generally, the reticulocytes are normal or reduced in number,<sup>11</sup> but sometimes they may be slightly increased.<sup>51</sup>

### Iron Metabolism

Characteristically, the serum iron is decreased, total iron-binding capacity is reduced, and transferrin saturation is subnormal (Fig. 18-3; also see Figs. 16-2 and 16-3, page 628).<sup>2,8</sup> In patients with infection, hypoferrinemia develops early in the course of the illness, frequently within 24 hours, and is observed even in acute, self-limited febrile diseases or following a single injection of typhoid vaccine.<sup>8,10,11</sup> Similarly, a rapid decrease in plasma iron follows the injection of either bacterial endotoxin,<sup>33</sup> or

Fig. 18-3 The serum iron and the total iron binding capacity of the serum in 13 patients with anemia associated with infection as compared with the normal and in six patients with iron-deficiency anemia.

Solid areas represent serum iron. Hatched areas represent the unsaturated iron-binding capacity. The total height of each column represents the total iron binding capacity of the serum. The figures above the columns represent the percent saturation (SI/TIBC). (From Cartwright et al.<sup>11</sup> courtesy of authors and *Journal of Clinical Investigation*.)

a substance similar to the "endogenous pyrogen" formed by neutrophilic leukocytes.<sup>46</sup> When the infection is of short duration, the serum iron returns to normal and anemia does not develop; in prolonged illnesses, the serum iron level remains low as long as the disease is active. When the disorder subsides, anemia often is relieved before the serum iron returns to normal. The degree of hypoferrinemia is related to the severity of the underlying illness.<sup>2,6,17,31</sup>

In bone marrow aspirates stained for iron, sideroblasts are found to be reduced to 5 to 20% of the total normoblasts (normal, 30 to 50%). In contrast, hemosiderin within macrophages usually is increased (Fig. 18-4); exceptions probably represent cases complicated by iron deficiency.

Absorption of iron from the gastrointestinal tract is reduced.<sup>8,11,13,27</sup> This abnormality appears to result from failure of the iron to

pass from the intestinal mucosal cell into the body.<sup>52</sup>

### Other Biochemical Findings

The concentration of free protoporphyrin in the erythrocytes (FEP) tends to increase in patients with chronic disorders<sup>10,32</sup> (Fig. 18-5). Levels of 36 to 634 µg per dl packed red cells (mean 180 µg), compared with normal values of 14 to 79 µg (mean 36 µg), were found in patients with infections.<sup>8</sup> The concentration of free erythrocyte coproporphyrin (FEC) was also increased, but only approximately twofold, rather than fivefold, and urinary excretion of coproporphyrin was increased. Unlike the change in serum iron, the FEP increases slowly and does not become clearly abnormal until significant anemia has developed.

In most patients with the anemia of

Fig 18-4. RE cell iron in bone marrow in 95 patients with chronic infection (dotted bars) compared with that found in 82 normal subjects (solid bars). The quantity present ranged from none (0) to heavy deposits (5 to 6+) (From Cartwright,<sup>8</sup> courtesy of the author and Henry M. Stratton Inc.)

chronic disorders, hypercupremia occurs. The levels associated with infection ranged from 118 to 267  $\mu\text{g/dl}$  (mean 191  $\mu\text{g/dl}$ ) compared with the normal range of 81 to 147  $\mu\text{g/dl}$  (mean 114  $\mu\text{g/dl}$ ).<sup>8,20</sup> This increase is due mainly to an increase in the plasma copper protein, ceruloplasmin (page 150). The hypercupremia precedes the development of anemia and, as the infection subsides, the copper content of the blood returns to normal more rapidly than does iron content of the serum.

#### Kinetic Characteristics

Ferrokinetic studies in patients with chronic infections,<sup>7,11,27,34</sup> rheumatoid arthritis,<sup>17,52,61</sup> and various malignant diseases<sup>30,42</sup> have shown that (1) the rate of disappearance of iron from the plasma is rapid, (2) the plasma iron transport rate is normal or slightly increased, (3) the uptake

of iron into erythrocytes and the amount of iron turning over through red cells daily are normal or increased, and (4) the fraction of red cells renewed daily is increased.<sup>8</sup> These findings indicate that erythropoiesis is normal or increased to only a moderate degree.

The rate of erythrocyte destruction is accelerated.<sup>7</sup> Erythrocyte survival, measured by the Ashby and <sup>51</sup>Cr-tagging procedures, is shortened modestly.<sup>8</sup> However, the usual manifestations of increased blood destruction, such as increased serum bilirubin and increased urobilinogen excretion, generally are absent.<sup>11,51</sup> The survival of cells from patients with arthritis, when transfused into normal subjects, has been found to be normal, and the survival of normal red cells in the circulation of patients with arthritis is less than normal.<sup>50</sup> These observations indicate that the accelerated breakdown of the red cells can be attributed to an extracorporeal factor.<sup>17</sup>

In summary, the kinetic data suggest that anemia develops because the bone marrow fails to increase red cell production sufficiently to compensate for a mild decrease in the life span of the red cells.

#### Pathogenesis

Three factors have been implicated in the pathogenesis of the anemia: (1) decreased erythrocyte life span, (2) impaired marrow response, and (3) unpaired flow of iron from reticuloendothelial stores to plasma.<sup>8</sup>

#### Erythrocyte Life Span

The kinetic studies cited in the preceding paragraphs indicate the presence of an extracorporeal factor acting to shorten erythrocyte survival. The nature of this factor remains unknown; however, a number of mechanisms have been suggested.<sup>8</sup> In animal studies, sterile, cell-free extracts of the viable portions of malignant tumors were found capable of hemolyzing red cells.<sup>55</sup> It also was shown that in vivo irradiation of normal or carcinomatous tissue can initiate a hemolytic mechanism.<sup>54</sup> Such observations led to the

Fig 18-5 The severe hypoferrremia increased plasma copper and increased erythrocyte protoporphyrin and urinary coproporphyrin in anemia associated with infection as indicated by a study of 50 cases (From Cartwright and Winrobe<sup>10</sup> courtesy of the authors and Year Book Medical Publishers, Inc.)

suggestion that hemolysins elaborated by the tumor may contribute to the anemia in cancer. Other studies suggested that vascular injury may be a factor in the pathogenesis of the erythrocyte destruction.<sup>47</sup> According to the latter hypothesis, red cells are destroyed as the result of leakage into the tumor. Still other studies have sought to discover the possible role of immune mechanisms, such as elaboration of autoantibodies by the malignant cells.<sup>22</sup> Bacterial toxins have been implicated as hemolytic factors in infections.<sup>34</sup> None of these explanations is entirely satisfactory. Furthermore, the similarity of findings in animals with sterile and bacterial abscesses and those in patients with the many and various diseases associated with the anemia of chronic disorders suggests that the mechanism may be the same in all these situations. It is possible that these diseases result in nonspecific stimulation of the reticulo-endothelial system, one consequence of which is an increase in this system's activity in destroying red cells.<sup>8,9</sup> Such a nonspecific

activation of macrophages (page 322) can be induced by a variety of stimuli, a phenomenon related to "cellular immunity."<sup>35</sup>

### Impaired Marrow Response

Normal bone marrow, being capable of a six- to eightfold increase in the red cell production rate, could easily compensate for the modest reduction in erythrocyte survival. Its failure to do so in the anemia of chronic disorders suggests that impaired production capacity is of fundamental importance in pathogenesis. The marrow response to anemia is under the control of erythropoietin (Chapter 4). Low serum erythropoietin levels in relation to the degree of anemia have been found in both man and experimental animals with this type of anemia.<sup>55,59</sup> Furthermore, such animals produced less than normal amounts of erythropoietin in response to hypoxia.<sup>37a</sup> However, if erythropoietin is administered, or if its endogenous elaboration is stimulated with cobalt or hypoxia, the

marrow is capable of responding to it.<sup>24,37a</sup> Thus, the defect in production appears to result from failure to secrete erythropoietin rather than from an inability of the marrow to respond to the hormone. It has been suggested that these observations reflect subtle alterations in control mechanisms, ie, "turning the hematologic thermostat down a bit," for the purpose of diverting substrates normally utilized in hemoglobin production to other, more critical, channels.<sup>9</sup>

### *Defective Iron Metabolism*

The alterations in iron metabolism appear to result from a block in the flow of iron from RE cells to plasma.<sup>8,16</sup> This block has been identified in several ways. With an <sup>59</sup>Fe label, reutilization of iron from effete red cells or hemoglobin solutions was found to be impaired.<sup>8,16,27,35,48,61</sup> A similar defect was observed when iron dextran was the iron source.<sup>4</sup> Such observations may be partly explained by dilution of the isotope by the increased stores of the reticuloendothelial cells,<sup>37</sup> but this explanation is not entirely satisfactory because it cannot account for the observation that the total amount of iron released following administration of damaged erythrocytes is subnormal.<sup>44</sup> A relatively simple way of demonstrating the reticuloendothelial iron block *in vivo* is to administer nicotinic acid intravenously, which induces a minor episode of hemolysis. In normal subjects the injection was followed by a prompt increase in serum iron; in patients with rheumatoid arthritis the increase was subnormal.<sup>45</sup>

As one consequence of RE iron blockade, erythropoiesis becomes limited by the insufficient iron supply,<sup>2</sup> accounting for the decreased marrow sideroblasts, the increased FEP, and the occasional occurrence of hypochromia. The nature of the relationship between the iron block and the defect in erythropoietin secretion requires further study. However, the observation that the anemia can be relieved by erythropoietin administration suggests that the hormone directly or indirectly relieves the block.<sup>9</sup>

One possible explanation for the abnormalities in iron metabolism is that they represent a mechanism which has evolved to defend the host against bacterial invasion.<sup>6a,57,60</sup> The low plasma iron value serves to inhibit bacterial growth. Furthermore, the increased RE iron may be useful in detoxifying virulent bacterial products.

### *Diagnosis*

In most instances, patients with anemia due to chronic disorders do not appear with anemia as the sole manifestation of illness. They are likely to complain of fever, chills, joint pains, weight loss, or other manifestations of the underlying illnesses. Only in the rare instances in which no specific signs or symptoms are present will difficulties in establishing the diagnosis arise. Under such circumstances, careful study of iron metabolism, as outlined in Chapter 16, should suggest the anemia of chronic disorders and distinguish it from that due to iron deficiency.

The next and most challenging step is the definition of the underlying disease. Little help in this direction is obtained from further study of the blood, for the anemia of chronic disorders is a nonspecific sign of disease, comparable to neutrophilic leukocytosis or accelerated erythrocyte sedimentation.

### *Treatment*

Correction of the anemia depends on relief of the primary disorder. Blood transfusion may be useful as a temporary measure, but the anemia is rarely so severe as to justify the expense, risks, and discomforts of transfusion. The anemia usually is not progressive and there is no evidence that it is harmful to the patient. General measures, as outlined in Chapter 13, should be employed. Vitamin B<sub>12</sub> and folic acid are of no value but, if there is an associated iron deficiency, as sometimes occurs, particularly in rheumatoid arthritis,<sup>59</sup> iron therapy may relieve the anemia to some degree.<sup>50</sup> Parenteral iron therapy should be avoided since, in the absence of associated iron deficiency, the tissues already are amply

supplied with iron. Iron given intravenously is rapidly shunted to the tissues without influencing the plasma iron level more than temporarily and without relieving the anemia<sup>11,62</sup>

Although cobalt (page 153), in the form of cobaltous chloride, 100 to 300 mg per day taken by mouth, will partially relieve the anemia associated with infection,<sup>5,19,62</sup> loss of appetite and other gastrointestinal symptoms are likely to occur, the effect of the treatment

disappears when use of the drug is discontinued, and no real benefit is achieved.

## Sideroblastic Anemias

The sideroblastic anemias are a heterogeneous group of disorders<sup>139,158</sup> that are characterized by the presence of excessive iron deposition within the mitochondria of normoblasts<sup>105,129,139,172,183</sup> (Fig. 18-6). Because of their characteristic perinuclear dis-

Fig 18-6 Excessive iron deposits in the mitochondria within normoblasts of a patient with sideroblastic anemia (Courtesy of WN Jensen)

tribution, these iron-laden mitochondria account for the so-called "ringed" sideroblast, a nucleated red cell in which Prussian blue-positive granules form a full or partial ring around the nucleus<sup>109</sup> (Plate X).

Mitochondrial iron excess appears to be a consequence of defective heme synthesis. Additional evidence of defective heme synthesis in sideroblastic anemia is found in the circulating red cells, which usually are hypochromic and microcytic. The degree of hypochromia and microcytosis varies considerably from one form of sideroblastic anemia to another. Often there is pronounced *dimorphism*, a hypochromic and/or microcytic population of cells existing side by side with a normal or even macrocytic one.

In addition to these morphologic findings, the sideroblastic anemias are characterized by a great increase in total body iron. Serum iron is increased, often to the point of complete saturation of transferrin. Excessive amounts of iron are deposited in cells of the reticulo-endothelial system and in the parenchymal cells of various organs. In some instances the excess iron appears to interfere with organ function, especially that of the liver, pancreas, and heart, resulting in the clinical picture of hemochromatosis.

These anemias are characterized kinetically by ineffective erythropoiesis.<sup>134,171,182</sup> Erythroid hyperplasia of the bone marrow is accompanied by a normal or only slightly increased reticulocyte count. The plasma iron transport rate is markedly increased, but red cell iron utilization is impaired. Red cell survival, as measured with the usual random labels (page 197), tends to be normal or only slightly reduced. There may be slight hyperbilirubinemia and an increase in urobilinogen excretion as the result of an increase in the erythropoietic component of the "early-labeled" bilirubin peak.<sup>102</sup> These findings suggest that many of the red cells formed from the maturation of ringed sideroblasts are essentially nonviable. Their destruction within the marrow or very shortly after their release accounts for the kinetic abnormalities.

Other terms used more or less synonymously with sideroblastic anemia include

*sideroachrestic anemia*,<sup>138</sup> and *iron-loading anemia*.<sup>113,130</sup> In addition, many of the cases formerly referred to as "*refractory anemia with hyperplastic bone marrow*"<sup>175</sup> probably belong in this category.

### Classification

There are many sideroblastic anemias and several classifications have been proposed.<sup>138,139,158</sup> For certain forms of sideroblastic anemia, the cause and pathogenesis seem reasonably well delineated. In others, the diseases must be defined on the basis of a combination of descriptive clinical, morphologic, and biochemical features. Consequently, continued refinement of any proposed classification scheme is to be expected.

In Table 18-2, the sideroblastic anemias have been divided into two major groups, depending on whether the illness appears to be inherited or acquired. Within the inherited group, an X-linked, often pyridoxine-responsive form has been delineated, which probably represents a congenital defect in the enzyme ALA synthetase.<sup>176</sup> In one family, a similar illness appeared to be inherited as an autosomal recessive trait.<sup>117</sup> In some patients, the finding of markedly increased erythrocyte coproporphyrin combined with reduced values for free erythrocyte protoporphyrin suggested that the enzyme coproporphyrinogen oxidase was defective.<sup>125,138</sup>

The acquired sideroblastic anemias are considerably more common than the inherited varieties. These may be subdivided on the basis of whether the anemia is of un-

**Table 18-2. Classification of the Sideroblastic Anemias**

A Hereditary sideroblastic anemia	
1	X linked
a	ALA synthetase deficiency <sup>176</sup>
b	(P) coproporphyrinogen oxidase deficiency <sup>125</sup>
2	Autosomal recessive <sup>117</sup>
B Acquired sideroblastic anemia	
1	Idiopathic refractory sideroblastic anemia <sup>145</sup>
2	Complicating other diseases <sup>139, 156</sup> (Table 18-3)
3	Associated with drugs or toxins (Table 18-4)

known cause (idiopathic) or associated with toxins or underlying diseases (Table 18-2).

### Hereditary Sideroblastic Anemia

This disorder was probably first described in 1946, under the name "hereditary (sex-linked) anemia," by Rundles and Falls.<sup>165</sup> Ten years later, Harris and coworkers reported the first case of so-called *pyridoxine-responsive anemia* in man.<sup>135</sup> Shortly thereafter, a member of one of the families studied by Rundles and Falls was found to be responsive to pyridoxine.<sup>106</sup>

Many of the patients with hereditary sideroblastic anemia have been reported as patients with pyridoxine-responsive anemia.<sup>134</sup> However, the degree to which hereditary sideroblastic anemia responds to pyridoxine varies considerably. In some patients, anemia has been corrected completely, others responded partially, and still others did not respond at all.

It is possible that these variations indicate fundamental differences in the nature of the disease; on the other hand, varying degrees of pyridoxine responsiveness have been observed within members of the same kindred.<sup>108,151</sup> Furthermore, responsiveness may decrease with subsequent courses of pyridoxine in the same patient.<sup>134</sup> Except for the response to therapy, there are no distinct clinical, hematologic, or biochemical differences between pyridoxine-responsive and refractory forms.

### Hereditary Pattern

Most patients with hereditary sideroblastic anemia have been males. Of 72 patients with "pyridoxine-responsive anemia," 22 (15 families) related a positive family history.<sup>134</sup> Only one of the 22 was female. Male subjects also predominated among the remaining patients. This male preponderance suggests that the disorder is inherited most commonly as an X-linked recessive trait. Several kindreds supporting such a mode of inheritance have been reported (Fig. 18-7).<sup>108,151,152,160,165,180</sup>

In such families, usually only male hemi-

zygotes have been anemic; however, morphologically abnormal erythrocytes have been found in female carriers. In exceptional families, the female carriers were moderately anemic,<sup>148,169,170</sup> and, in at least one such family, the abnormal red cell population appeared to be so severely lacking in hemoglobin that the trait would probably have been lethal in males.<sup>145</sup> In this family, the X-linked red cell antigen, Xg<sup>a</sup>, was found on the abnormal cells only; normal cells were Xg<sup>a</sup>-negative. These observations were interpreted as supporting an X-linked mode of inheritance, with mosaicism in the female patient on the basis of X-inactivation. A similar distribution of the Xg<sup>a</sup> antigen could not be demonstrated in two other families<sup>160,170</sup>; however, the abnormal cell populations were not as severely affected, and appeared not to have been completely separated from the normal one for study.

In one reported family, a brother and sister were affected equally, suggesting autosomal inheritance.<sup>117</sup>

### Clinical Picture

The anemia may be apparent at birth or in infancy, but the onset most often occurs in young adulthood.<sup>134</sup> Exceptionally, the anemia is not discovered until after the subject has reached the age of 60 years. Such variations may occur even within a single kindred.<sup>151</sup> The factors that delay the onset of this inherited condition have not been completely defined. Unusually high dietary or medicinal pyridoxine intake may be one such factor.<sup>163</sup> The degree of iron overload may be another.<sup>176,180</sup>

In addition to the signs and symptoms of anemia, most patients exhibit manifestations of iron overload. Mild to moderate enlargement of the liver and spleen is common; however, liver function usually is normal or only mildly disturbed. Liver biopsy reveals excessive iron in both parenchymal and RE cells with a variable amount of fibrosis.<sup>134</sup> Frank clinical diabetes or abnormal glucose tolerance may be detected in as many as one third of the patients. Occasionally, abnormal

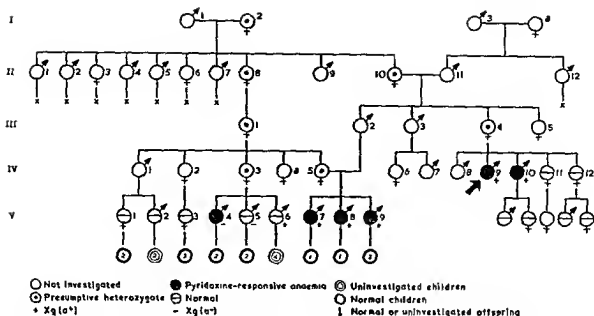

Fig. 18-7 Pedigree of a family with hereditary sideroblastic anemia (From Elves et al.<sup>123a</sup> courtesy of the authors and Journal of Medical Genetics)

skin pigmentation is observed. The most dangerous manifestations of iron overload are disturbances of cardiac rhythm; fortunately, these tend to be relatively uncommon and to occur late in the course of the disease.

Signs and symptoms of nutritional deficiency are absent. In particular, neurologic and cutaneous manifestations of vitamin B<sub>6</sub> deficiency (page 144) are not observed.

### Laboratory Findings

The anemia usually is severe (average blood hemoglobin 6.5 g/dl), and hypochromia and microcytosis are pronounced (Table 16-3, page 626).<sup>134</sup> Anisocytosis, poikilocytosis, target cells, and basophilic stippling are prominent findings on blood smear (Fig. 18-8), and erythrocyte dimorphism is common. Leukocytes and platelets usually are normal. Erythroid hyperplasia is found on marrow examination, and maturation usually is normoblastic; occasionally, megaloblastic changes are observed,<sup>134</sup> probably because of complicating folate deficiency.

Transferrin saturation almost invariably is increased. Excessive hemosiderin stores are found in marrow. Ringed sideroblasts consti-

tute about 10 to 40% of the normoblasts. The ringed forms usually are found in the polychromatophilic or orthochromic stages of normoblast maturation.<sup>133</sup>

Kinetic evidence of ineffective erythropoiesis usually can be demonstrated.

In about one third of the patients, abnormal tryptophan metabolism, as indicated by the excessive urinary excretion of xanthurenic and/or kynurenic acid following a tryptophan load, has been observed. These abnormalities have been interpreted as evidence of deficiency or abnormal metabolism of vitamin B<sub>6</sub>. However, they may also occur nonspecifically as the result of induction of hepatic tryptophan pyrrolase.<sup>101</sup>

The free erythrocyte protoporphyrin (FEP) level tends to be reduced or low normal.<sup>134,161,175</sup> In isolated red cell populations from a female patient, the FEP was very low in the microcytic cells and normal in the normocytic ones.<sup>145</sup> Erythrocyte coproporphyrin (FEC) usually is normal; however, in an unusual patient reported by Garby and coworkers, the low FEP was accompanied by very high FEC values.<sup>125</sup> Heilmeyer, drawing on clinical material from all over Europe, found porphyrin alterations similar to those

Fig. 18-8 Blood smears of a patient (E O R) with pyridoxine-responsive anemia. The smear on the right was made after pyridoxine 100 mg daily, had been given intravenously for 30 days and the hemoglobin had risen from 7.7 to 9.8 g/dl (From Raab et al,<sup>141</sup> courtesy of the authors and Henry M. Stratton, Inc.)

reported by Garby and associates in six additional patients, all males.<sup>138</sup>

### Treatment

Pyridoxine therapy should be tried in all patients. Doses of 50 to 200 mg/day usually are administered. There is no convincing evidence that the parenteral route is more effective than the oral one. These doses are very large as compared with the estimated adult daily requirement for vitamin B<sub>6</sub> of 1.5 to 2 mg. As previously noted, the response to pyridoxine is variable. In somewhat less than half of the patients an "optimal response" is observed: reticulocytosis occurs, the blood hemoglobin returns to normal or near normal levels, the serum iron decreases, the FEP increases,<sup>148,161</sup> and abnormalities in tryptophan metabolism are corrected. However, morphologic abnormalities of the red cells never completely disappear (Fig. 18-8).<sup>134</sup> Of the patients in whom optimal response is not obtained, some experience distinct, but suboptimal improvement when pyridoxine is given, and the blood hemoglobin stabilizes at less than normal levels.

Still others have not responded at all, including all of those with high FEC levels.<sup>133</sup>

Once the maximal effect of pyridoxine has been achieved, continued maintenance doses are required. Relapse usually will follow within several months after discontinuing treatment.<sup>134,161</sup> After relapse, it may be possible to induce additional remissions with pyridoxine, but in some instances the response was less satisfactory than with the first course of therapy.<sup>134</sup> In one patient, responsiveness to pyridoxine was restored by administration of the amino acid, L-tryptophan.<sup>142</sup>

If megaloblastic changes are present, folic acid should be added to the regimen. Usually such therapy leads to normoblastic maturation, suboptimal reticulocytosis, and an increase in hemoglobin levels. Of special interest is an occasionally observed response to Valentine's crude liver extract, possibly to an indole contained therein.<sup>134,142</sup> In one report, a patient who responded to an unidentified material in human plasma was described.<sup>124</sup> Androgens also may be effective.<sup>126</sup>

In several patients, the effect of removal of excess body iron was assessed.<sup>134,176,180</sup>

The results were variable. In general, after excess iron was removed, pyridoxine was still required, but at times somewhat greater hemoglobin levels could be maintained. Serum iron values were clearly lower,<sup>134</sup> and *in vitro* heme synthesis was improved.<sup>176</sup> Even if there is no hematologic improvement, the risk of hemochromatosis is eliminated. Thus, in patients who can tolerate it, removal of the excess iron should be seriously considered.

The course is variable and the prognosis must be guarded. Those patients who respond well to pyridoxine may live comfortably for many years.<sup>134</sup> Others have died after having become refractory to therapy, usually because of cardiac arrhythmias, liver failure, bone marrow failure, or infections.

### Pathogenesis

Patients with hereditary sideroblastic anemia exhibit many of the features of experimentally induced vitamin B<sub>6</sub> deficiency in swine (Chapter 4). They differ in that (1) evidence of nutritional deprivation is lacking, (2) unusually large amounts of vitamin B<sub>6</sub> (pyridoxine) are required for correction of the syndrome, and (3) response is incomplete.

Pyridoxal-5-phosphate, the coenzyme form of vitamin B<sub>6</sub>, is required for the synthesis of delta-aminolevulinic acid.<sup>167</sup> This reaction occurs within mitochondria and is the first step in porphyrin biosynthesis (Chapter 4). Indirect evidence suggests that hereditary sideroblastic anemia arises from a genetic defect in this step.<sup>146</sup> Such a defect could account for the anemia, the hypochromia, the reduced FEP, the mitochondrial iron accumulation, and the response to pyridoxine. Presumably the genetic lesion affects the enzyme, ALA synthetase.<sup>176</sup> Although it may seem peculiar that large doses of a cofactor could compensate for an enzymatic deficiency, there are other inherited disorders in which pyridoxine seems to exert a similar effect, including "pyridoxine-dependent" seizures in children, and cystathioninuria.<sup>146,168</sup> It is to be expected that, as in other inherited enzymatic deficiencies, several

allelic variants may exist, accounting for the variability in clinical severity and pyridoxine responsiveness.

It seems likely that the children, described above, with high FEC values have a defect of a different sort, namely, in the conversion of coproporphyrinogen to protoporphyrin (the coproporphyrinogen oxidase reaction).<sup>125,138</sup> This step does not require pyridoxal phosphate as a cofactor, and such children are refractory to pyridoxine therapy.

### Idiopathic Refractory Sideroblastic Anemia (IRSA)<sup>145</sup>

First described by Bjorkman<sup>107</sup> and by Dacie and associates,<sup>119</sup> this form of sideroblastic anemia has also been called "refractory normoblastic anemia,"<sup>119</sup> "anemia refractoria sideroblastica,"<sup>136,138</sup> "idiopathic ineffective erythropoiesis,"<sup>117</sup> and "primary acquired refractory sideroblastic anemia."<sup>139</sup> Although accurate incidence figures are not available, the illness appears to be uncommon but not rare.<sup>145</sup> The cause and pathogenesis are unknown, but the descriptive features appear to be sufficiently characteristic to define the illness as a distinct entity.

### Clinical Features

IRSA is a disease of older adults. In a group of 61 patients, the average age at the time of presentation was 66 years,<sup>145</sup> and very few patients less than 50 years of age have been reported. The anemia develops insidiously and often is discovered at the time of a routine examination or in association with an unrelated complaint. Some patients complain of mild symptoms of anemia. The physical examination often reveals no abnormality except for slight pallor, but hepatosplenomegaly of mild degree is found in about 40% of the patients.

### Laboratory Findings

The anemia usually is moderate in degree (mean VPRC 0.27 l/l) and normocytic or macrocytic (mean MCV 100 fl) in type (Fig.

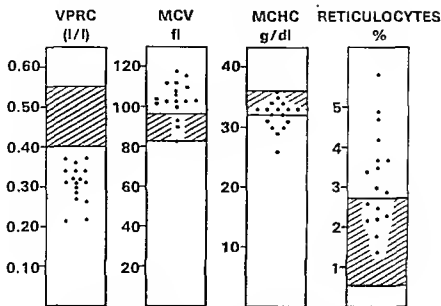

Fig 18-9. Characteristics of the anemia in 17 patients with IRSA.<sup>145</sup> The anemia was usually macrocytic and either normochromic or slightly hypochromic. The reticulocyte count was within the normal range or slightly above it. The normal range (mean  $\pm$  2 SD) is indicated by the shaded areas. VPRC: Volume of packed red cells; MCV: mean corpuscular volume; MCHC: mean corpuscular hemoglobin concentration. (From Kushner et al,<sup>145</sup> courtesy of the authors and William & Wilkins Co.)

18-9) The MCHC is normal or slightly reduced, but a small population of hypochromic cells is found on blood smear in all the subjects. A particularly characteristic finding is the presence of occasional, heavily stippled, hypochromic cells. Leukocyte and platelet counts usually give values within the normal range, but modest leukopenia and/or thrombocytopenia may be found. Leukocyte alkaline phosphatase is reduced in about half of the patients.

Erythroid hyperplasia (average M:E ratio, 1.1:1) is found on bone marrow examination. A feature which may be helpful in distinguishing IRSA from erythroleukemia is the lack of PAS-positive material in the normoblasts. Megaloblastic changes, correctable with folate administration, are found in 20% of patients with IRSA. Marrow hemosiderin is almost always increased and ringed sideroblasts comprise 43 to 95% of the normoblasts. In contrast to hereditary or secondary sideroblastic anemias, the early (basophilic) normoblasts may be ringed.<sup>133</sup>

Transferrin saturation is increased in nearly all patients and exceeds 90% in about one third of the patients.<sup>145</sup> Marked deposition of iron is found in the liver, but hepatic dysfunction is rare.

Free erythrocyte protoporphyrin (FEP) characteristically is increased to 46 to 300  $\mu\text{g/dl}$  (normal 16 to 36  $\mu\text{g/dl}$ ). In one patient very high values were found (1700  $\mu\text{g/dl}$ ), and this abnormality was associated with dermal photosensitivity.<sup>164</sup> If pyridoxine is administered, a further increase in FEP occurs.

There may be modest increases in serum bilirubin (no greater than 2.0 mg/dl) and in urobilinogen excretion. The kinetic pattern is that found with ineffective erythropoiesis.

#### Treatment and Prognosis

A therapeutic trial of pyridoxine, 50 to 200 mg per day, is indicated, but most patients do not respond,<sup>145</sup> and in those who do the response is minimal.<sup>139</sup> However, about half

of the patients with IRSA are not severely incapacitated by their anemia. Furthermore, there may be no progression for a number of years. In such patients, no therapy is required. On the other hand, if the VPRC tends to fall to levels at which significant cardiovascular symptoms occur, treatment may be necessary. Sometimes, transfusion of packed red cells is the only means of relieving the anemia, but transfusion therapy should be kept to a minimum since it will add to the iron overload. A proportion of patients respond to large doses of androgens (eg, 50 to 300 mg of oxymetholone per day),<sup>145</sup> and a trial of such therapy is warranted in patients who require transfusions.

The median survival of patients with IRSA was 10 years<sup>145</sup>; it was longer in patients who did not require transfusion (15 years) than in those who did (eight years). In some cases (about 7%), the terminal events were marked by the onset of leukemia, usually of the acute myelomonoblastic type.

### **Etiology and Pathogenesis**

The cause of IRSA remains unknown. Because of the age distribution and lack of affected relatives, it is assumed to be an acquired disorder. Suggested etiologic factors include neoplasia<sup>121</sup>; hypersensitivity reactions to drugs, toxins, or environmental pollutants; deficiency of an unknown nutrient; and somatic mutation.<sup>145</sup> The available data do not affirm the etiologic role of, or exclude the possibility of, any of these. Because of the observed increase in FEP, it has been proposed that the *heme synthetase reaction*, in which protoporphyrin is converted to heme, is impaired.<sup>138</sup> In one unique patient, the value for FEP was unusually high and heme synthetase activity was reduced in reticulocytes, possibly because of deficiency of a hypothetical cofactor.<sup>164</sup> However, in other patients with IRSA, no defect in reticulocyte heme synthetase could be found.<sup>145,173</sup> Indeed, assays of the entire heme biosynthetic pathway in circulating erythrocytes gave normal values.<sup>145,173</sup> On the other hand, in vivo studies of incorporation of glycine and

valine into hemoglobin in patients with IRSA suggested that globin synthesis was normal and that heme synthesis was defective.<sup>177</sup> Additional indirect evidence supporting such a defect is the observation that heme-free  $\alpha\beta$ -globin dimers could be demonstrated in reticulocytes from patients with IRSA and that the addition of heme in vitro removed the free dimer and greatly stimulated globin synthesis.<sup>181</sup>

### **Sideroblastic Anemia as a Complication of Other Diseases**

So-called "secondary" or "symptomatic" sideroblastic anemia has been observed in association with a wide variety of illnesses (Table 18-3). This type of anemia is common, but poorly characterized and incompletely understood. In most instances the clinical picture is dominated by signs and symptoms of the underlying disease. The presence of anemia, occasional hypochromic cells on blood smear, and ringed sideroblasts in the marrow establishes the diagnosis. In some patients with leukemia,<sup>114</sup> myeloma,<sup>102,114</sup> or

**Table 18-3. Diseases Which May Be Complicated by Sideroblastic Anemia**

<b>A Diseases of the blood and blood forming organs</b>	
1	Leukemia <sup>114 170</sup>
2	Polycythemia vera <sup>139 156</sup>
3	Myelofibrosis <sup>139 156</sup>
4	Hemolytic anemia <sup>156 159</sup>
5	Pernicious anemia and other megaloblastic anemias <sup>154</sup>
<b>B Neoplastic diseases</b>	
1	Hodgkin's disease <sup>119</sup>
2	Other lymphomas <sup>109</sup>
3	Carcinoma <sup>139 147 154</sup>
4	Multiple myeloma <sup>102 114 144</sup>
<b>C Inflammatory diseases</b>

2	Polyarteritis nodosa <sup>154</sup>
3	Infection <sup>109 110 146</sup>
<b>D Miscellaneous disorders</b>	
1	Myxedema <sup>139 154</sup>
2	Thyrotoxicosis <sup>139</sup>
3	Uremia <sup>122 139</sup>
4	Erythropoietic porphyria <sup>131 137</sup>
5	Porphyria cutanea tarda <sup>129</sup>

metastatic carcinoma,<sup>147</sup> sideroblastic anemia was present for several months before the underlying disease became apparent.

In general the number of ringed sideroblasts and the degree of hypochromia, hyperferremia, iron overload, and ineffective erythropoiesis are less than in other sideroblastic anemias. Complicating megaloblastosis with decreased serum folate levels is common.<sup>150</sup>

The treatment, course, and prognosis are related to the nature of the associated disease. When the disease can be cured or relieved, the sideroblasts may disappear from the marrow, and the anemia may lessen or disappear without other therapy. Such a course has been observed, for example, in infectious diseases<sup>110,160</sup> or with the induction of remission in leukemia.<sup>170</sup> In other instances, improvement in the anemic state has been observed when folic acid, pyridoxine, or both were administered.<sup>139,156</sup> In general, folic acid is most likely to be effective when there is megaloblastosis and subnormal serum folate levels. Even under such circumstances, however, the response may be incomplete. In only a few patients have large doses of pyridoxine induced even modest increases in the hemoglobin level.<sup>139</sup> Sideroblastic anemia in myeloma may be a preleukemic change.<sup>144</sup>

It has been suggested that "secondary" sideroblastic anemia results from conditioned pyridoxine deficiency in a manner analogous to the development of folate deficiency in association with chronic hemolytic disease (page 579).<sup>156</sup> This hypothesis is supported by the relatively frequent association with evidence of folate lack. Also cited in support of this hypothesis is the high incidence of abnormalities in tryptophan metabolism<sup>156</sup>; however, these are more likely to be a manifestation of nonspecific induction of hepatic tryptophan pyrrolase than of pyridoxine deficiency.<sup>101</sup>

#### Sideroblastic Anemia Associated with Drugs and Toxins

Drugs and toxins that have been reported to cause sideroblastic anemia are listed in Table 18-4.

**Table 18-4. Drugs and Toxins Which May Produce Sideroblastic Anemia**

---

1	Ethanol <sup>123,141</sup>
2	Drugs used in therapy of tuberculosis <sup>132,139,154,155,174</sup>
3	Lead <sup>104,127</sup>
4	Chloramphenicol <sup>103,139,157,140</sup>
5	Drugs used in therapy of neoplastic diseases nitrogen mustard <sup>109</sup> melphalan, <sup>144</sup> azathioprine <sup>118</sup>

---

#### Alcoholism

Sideroblastic anemia occurs in about 30% of alcoholics who become ill enough to require hospitalization.<sup>123</sup> Blood hemoglobin ranges from 6 to 10 g/dl and pronounced dimorphism of circulating erythrocytes is observed.<sup>141</sup> The MCV is normal or increased, and the MCHC is normal or slightly reduced.<sup>123</sup> Transferrin saturation is increased (mean 80%) and 8 to 65% of the normoblasts are ringed sideroblasts, especially those in the polychromatophilic and orthochromic stages. Marrow hemosiderin stores are increased. These changes are almost always accompanied by vacuolization of the erythrocyte precursors<sup>150</sup> and by megaloblastic erythropoiesis, hypersegmentation of neutrophils, and reduced serum and red cell folate levels.<sup>141</sup> In controlled, sequential studies, the megaloblastosis preceded the sideroblastic changes.<sup>123</sup>

Withdrawal of alcohol is followed by a reticulocytosis that reaches a peak after five to 10 days, and by disappearance of ringed sideroblasts and an increase in blood hemoglobin levels.<sup>123,141</sup> Furthermore, the vacuolization and megaloblastosis of erythrocyte precursors disappear, and serum and red cell folate levels gradually increase.

Parenteral administration of pyridoxal-5-phosphate, the coenzyme form of vitamin B<sub>6</sub>, leads to remission, even if alcohol intake continues, but neither folate nor pyridoxine is effective under such circumstances.<sup>141</sup> This observation suggests that alcohol exerts an inhibitory effect on conversion of pyridoxine to the active coenzyme form.

Fig. 18-10. Symptoms (left) and signs (right) in 50 cases of lead poisoning (From Dagg et al.<sup>120</sup> courtesy of the authors and Oxford University Press)

### Agents Used in Therapy of Tuberculosis

Sideroblastic anemia has been described in association with the treatment of tuberculosis with isonicotinic acid hydrazide (INH), pyrazinoic acid, and cycloserine, alone or in combination.<sup>132,134,135,174</sup> The number of reported cases is small in relation to the widespread use of these agents, suggesting that the complication is a rare one. In the reported cases, anemia was moderately severe (VPRC 0.20 to 0.26 l/l), and hypochromia was prominent on blood smear. Transferrin saturation was normal in some subjects, but increased in most. Ringed sideroblasts were invariably present in the bone marrow. Withdrawal of the offending drug led to reticulocytosis and gradual improvement in the VPRC. Alternatively, a similar response could be induced by administering large doses of pyridoxine while continuing the tuberculostatic drug.

It is probable that these drugs induce sideroblastic anemia by interfering with vitamin B<sub>6</sub> metabolism. INH reacts with pyridoxal to form a hydrazone, which is an inhibitor of pyridoxal kinase,<sup>153</sup> an enzyme required for the conversion of vitamin B<sub>6</sub> to its active coenzyme form. Cycloserine is an *in vitro* inhibitor of pyridoxal-dependent en-

zymes.<sup>112</sup> Serum pyridoxal concentrations were found to be subnormal in patients receiving INH.<sup>140</sup>

The relative rarity of the syndrome suggests that there may be additional unknown factors, perhaps genetic or nutritional, that render certain patients unusually susceptible to the antipyridoxine effects of the drugs.

### The Anemia of Lead Poisoning

Anemia is one of the most common manifestations of chronic lead poisoning (plumbism)<sup>120</sup> (Fig. 18-10). In experimental animals, lead administration induces an excess accumulation of iron within mitochondria of erythrocyte precursors.<sup>128,143</sup> In some human subjects with lead intoxication, ringed sideroblasts have been observed.<sup>104</sup> For these reasons, and also because the inhibitory effects of lead on heme synthesis have been well documented,<sup>100,127</sup> the anemia may be tentatively included among the sideroblastic anemias. Admittedly, however, a sizable series of patients has not yet been studied with respect to the incidence and degree of sideroblastic changes in the bone marrow.

Lead poisoning occurs in adults chiefly as the result of industrial exposure. In children with pica, intoxication may develop because of ingestion of lead-containing paint. The

**Table 18-5. Hematologic Changes in the Anemia of Lead Poisoning in Adults<sup>120,130</sup>**

	<i>Normal</i>	<i>Lead Poisoning</i>
Hemoglobin (g dl)	♂ 14-18 ♀ 12-16	10.7 (8-13)
VPRC (l/l)	♂ 0.40-0.54 ♀ 0.37-0.47	0.35 (0.29-0.43)
MCV (fl)	89 (83-96)	79 (70-92)
MCHC (g dl)	34 (32-36)	31 (27-36)
Reticulocytes (%)	1.6 (0.6-2.7)	4.4 (1.5-11.6)
Stippled cells (%)	rare	1.8 (0.1-7.5)
Leukocytes ( $\times 10^9/l$ )	4-11	4-15

principal manifestations are abdominal ("lead colic") and neurologic (Fig. 18-10), and the clinical picture bears some resemblance to that of acute intermittent porphyria (Chapter 42).<sup>120</sup>

The severity of the anemia ranges from mild to moderate and the red cells tend to be mildly hypochromic and microcytic (Table 18-5). In children, the morphologic changes are more pronounced than in adults, probably because of complicating iron deficiency.<sup>178</sup> The reticulocyte count usually is only slightly increased, but it may be greater in rare patients with overt hemolytic anemia.<sup>120</sup> Basophilic stippling may be prominent, but it is not always found nor does it correlate in degree with the intensity of lead exposure.<sup>130</sup> The stippling results from aggregation of ribosomes.<sup>100,141</sup> Osmotic fragility of the erythrocytes is decreased, and a further decrease occurs after 24 hours of sterile incubation.<sup>130</sup> Mechanical fragility is increased.<sup>130</sup> An electrophoretically "fast" hemoglobin similar to hemoglobin A<sub>3</sub> (page 172) may be found.<sup>115</sup> In about 15% of patients, an increased proportion of hemoglobins A<sub>2</sub> or F has been reported.<sup>100</sup> Erythroid hyperplasia is observed in bone marrow. Plasma iron levels tend to be normal or

slightly increased in adults,<sup>100,111</sup> and reduced in children, probably because the latter are deficient in iron.<sup>178</sup> Elevated plasma and urine lead levels (greater than 0.08 mg/24 hr) establish the diagnosis. When urinary lead excretion is borderline, the diagnostic accuracy may be improved by measuring urinary lead following an injection of 0.5 g calcium EDTA. Excretion of more than 0.8 mg of lead in 24 hours following the injection establishes the diagnosis.<sup>100</sup>

Studies of erythrokinetics in lead poisoning have demonstrated about a 20% decrease in mean red cell life span.<sup>101,111</sup> The pattern of destruction is random rather than senescent. Since the rate of <sup>51</sup>Cr elution from red cells is accelerated in lead poisoning, the rate of red cell destruction is overestimated with this isotope.<sup>101</sup> These effects probably result from damage to the red cell membrane.<sup>100</sup> Plasma iron turnover may be slightly decreased.<sup>104,111</sup> There is an increase in the "early labeled" bile pigment.<sup>104</sup> These kinetic findings suggest ineffective erythropoiesis accompanied by mild hemolysis.

Abnormalities in porphyrin metabolism<sup>127,130</sup> include greatly increased urinary delta-aminolevulinic acid (ALA) with normal levels of porphobilinogen (PBG). This combination of findings helps to distinguish plumbism from acute intermittent porphyria (Chapter 32), in which both PBG and ALA are excreted in excess. In plumbism, there is also an increase in urinary coproporphyrin and, to a lesser degree, urinary uroporphyrin. Free erythrocyte protoporphyrin is greatly increased. Stool porphyrins are normal. The abnormalities are presumed to result from the effects of lead on essential sulfhydryl groups of the heme biosynthetic enzymes. This presumption has been best established in the case of ALA dehydrase.<sup>116,149</sup> Heme synthetase probably is also affected.<sup>116,127</sup> The excessive urinary coproporphyrin excretion suggests that coproporphyrinogen oxidase activity may be inhibited by lead.<sup>116</sup>

Treatment of patients with lead poisoning requires the administration of chelating agents, especially calcium sodium ethylenediamine tetraacetic acid (EDTA). Since the lead chelate is also toxic, there may be a

Fig 18-11 Lead "line" in a patient with plumbism. Under a hand lens the lead line of blue-black lead sulfide, actually deposited in the gums immediately opposite to the teeth, appears as a clear row of dots or vertical streaks. (From Beiknap,<sup>101a</sup> courtesy of the author and the Journal of the American Medical Association.)

transient increase in encephalopathy and porphyrin excretion,<sup>116</sup> but this is less likely to occur if less than 0.5 to 1.0 g per day is given.<sup>100</sup> With EDTA treatment there is rapid urinary excretion of lead. Urine ALA, PBG, and coproporphyrin levels return to normal within several days, and the hemoglobin may reach normal in several weeks.<sup>104</sup> However, the damage to circulating red cells is not corrected, and the shortened life span may therefore continue until the defective cells are replaced with normal ones.

### Other Drugs

Sideroblastic anemia has been reported in several patients given chloramphenicol in total doses of 17 to 56 g.<sup>103,129,139,140</sup> The abnormalities disappeared when the drug was withdrawn. Chloramphenicol may act by inhibiting the synthesis of mitochondrial proteins, including heme synthetase.<sup>157</sup> There is no demonstrated connection between this syndrome and chloramphenicol-induced aplastic anemia (page 1750).

Transient sideroblastic changes have been observed as a response to antineoplastic agents, such as nitrogen mustard<sup>109</sup> and azathioprine.<sup>118</sup> Similarly, sideroblastic anemia

has been observed as a complication in patients with myeloma treated with melphalan.<sup>141</sup> In this latter group, leukemia often developed within several months.

# The Normocytic, Normochromic Anemias

### Classification and Diagnostic Approach

Acute Posthemorrhagic Anemia

Congenital Dyserythropoietic Anemias

The Anemia of Chronic Renal Insufficiency

Anemia in Cirrhosis and Other Liver Dis-

orders

Anemias Associated with Endocrine Dis-

orders

THE normocytic, normochromic anemias are those in which the MCV and MCHC are within normal limits or, at least, do not deviate greatly from normal. One problem in approaching and classifying the anemias that fall into this category is that many of them have variable morphologic characteristics. Thus, for example, the anemias associated with myxedema, liver disease, or acute hemorrhage may be either normocytic or slightly macrocytic. These anemias have been included in this chapter because their most common or least complicated presentation is that of a normocytic normochromic anemia. On the other hand, the anemia of chronic disorders, although most often normocytic and normochromic, is more conveniently discussed with the hypochromic microcytic anemias because the pathogenesis of the disorder and the tests used in its detection and diagnosis are best understood in that context (Chapters 16 and 18). In still other disorders, such as iron deficiency, the typical morphologic features become apparent only when

the condition is fully developed, and early in the course the anemia may be normocytic and normochromic.

Another problem that complicates understanding of the normocytic normochromic anemias is that they, in contrast to the macrocytic anemias (Chapter 14) or the hypochromic, microcytic anemias (Chapter 16), are not clearly related to one another by common pathogenetic mechanisms. Instead, they constitute a group of remarkably diverse etiologic background. In many instances the anemia is of only incidental importance, ie, a minor manifestation of a systemic disease with other, more serious consequences. Sometimes, however, it is the first evidence of the disease and the sign leading to investigations resulting in the discovery of the underlying disorder.

## Classification and Diagnostic Approach

Despite the varied etiologic background and the often incidental nature of the normocytic anemias, it is possible to classify them in a way that forms a basis for diagnostic investigation (Table 19-1).

As a first step, the physician should determine whether the marrow response is appropriate to the degree of anemia. When bone marrow function is unimpaired, erythropoiesis can increase six- to eight-fold and the M:E ratio becomes reduced because of ac-

**Table 19-1. Classification of the Normocytic, Normochromic Anemias**

celerated proliferation of erythroid elements. Fortunately, it is rarely necessary to resort to marrow examination to evaluate marrow response. The most useful signs are found in the blood, where *reticulocytosis* is prominent and, on routinely stained smears, polychromatophilic macrocytes are detected. Ferrokinetic studies, also rarely necessary, disclose increased rates of plasma and erythroid iron turnover (Table 19-2, Hemolytic Anemia). These manifestations of appropriate marrow response are typical of hemolytic anemia (Chapter 20) and, to a somewhat lesser extent, posthemorrhagic anemia (page 695). The history, physical examination, and the signs of excessive erythrocyte destruction, such as hyperbilirubinemia and excessive urobilinogen excretion, easily differentiate these two conditions.

When anemia is found and the erythropoietic response described above is lacking, it may be presumed that the underlying disorder directly or indirectly affects the bone marrow. Suspicion of *intrinsic marrow disease* should be particularly great when there is

associated leukopenia and thrombocytopenia, or when morphologic abnormalities suggestive of marrow infiltration are found on the blood smear. These include nucleated red cells, "tear-drop" poikilocytes, immature leukocytes, and large, bizarre platelets or megakaryocyte fragments. With either type of change, marrow aspiration and biopsy should be performed. Hypoplasia is easily detected by this procedure, and infiltrating elements may be demonstrated. The dyserythropoietic anemias may be identified by the presence of prominent multinuclearity of the marrow normoblasts.

When no intrinsic disease is apparent on study of the marrow, an *indirect effect on erythrocyte production* should be considered. Several disorders are associated with reduced secretion of the erythropoietic hormone, erythropoietin (Table 19-1). Erythropoietin assays are not generally available, but fortunately it is not necessary for diagnostic purposes to establish that erythropoietin levels are low in these conditions, because screening tests usually will uncover an underlying sys-

temic disease (Table 19-1, B2). For this purpose, the functions of the kidneys, liver, and thyroid gland should be assessed by means of appropriate biochemical tests. Although severe protein-caloric malnutrition is accompanied by reduced erythropoietin secretion and a mild normocytic anemia (Chapter 4), such undernutrition is rare in temperate countries and unlikely to be confused with other systemic disorders. Finally, it is helpful to study the serum iron and iron-binding capacity, for these, in conjunction with marrow iron stains, should make it possible to detect either the anemia of chronic disorders or early iron deficiency (Chapter 16). This diagnostic approach is outlined in Figure 19-1.

## Acute Posthemorrhagic Anemia

The anemia caused by blood loss occurs in association with a large variety of underlying diseases. Bleeding may be obvious as, for example, when profuse hemorrhage occurs from a body orifice or from an external wound. Alternatively, when bleeding occurs

within the gastrointestinal body cavity or tissue space, the problem may not be immediately apparent and may present a diagnostic challenge. Certain causes of hemorrhage are unique to the newborn; these have been discussed in Chapter 13 (page 560) and are listed in Table 13-1.

When the blood loss occurs in small amounts over a prolonged period of time, no anemia develops until iron stores have been depleted. In such circumstances, the hematologic findings are those of iron-deficiency anemia (Chapter 17). On the other hand, when larger amounts of blood are lost, anemia may develop even though iron stores remain adequate. This latter type is designated *acute posthemorrhagic anemia*.

### Clinical Description

The manifestations of hemorrhage depend on the rate and magnitude of the bleeding, the time elapsed since it took place, and whether it is external or occult. In addition, the presence of complicating diseases and the cardiovascular status of the patient, as well as his age, nutritional adequacy, and emo-

tional stability, may modify the response to bleeding

Following a single acute hemorrhage of brief duration, a characteristic sequence of events is observed, which may be divided into two phases. The first phase, lasting about one to three days, is dominated by manifestations of hypovolemia, and there may be little or no anemia. The second phase, which follows restoration of the blood volume to near normal levels, is characterized by anemia and signs of active erythrocyte regeneration. When the hemorrhage is prolonged or recurrent, manifestations of hypovolemia and those of regenerative anemia may occur at the same time, or may wax and wane.

Most young, healthy subjects can tolerate the rapid loss of 500 to 1000 ml of blood (10 to 20% of the blood volume) with few, if any symptoms.<sup>1</sup> However, approximately 5% of the population experience a "vasovagal reaction" to blood loss of this magnitude.<sup>2,10</sup>

The reaction consists of weakness, sweating, nausea, and a fall in heart rate and blood pressure, often followed by lightheadedness and loss of consciousness (syncope or fainting). Whether these subjects react as they do because of physiologic or psychic differences in their makeup is unknown; however, they exhibit two dominant personality traits: hypochondriasis and a tendency to react to stress with hopelessness, depression, or despair.<sup>10</sup>

With the rapid loss of 1000 to 1500 ml of blood (20 to 30% of the blood volume), previously healthy subjects remain asymptomatic while at rest in a recumbent position but may experience lightheadedness and hypotension when upright. They also respond to exertion with an unusual degree of tachycardia.<sup>3</sup>

When 1500 to 2000 ml (30 to 40% of the blood volume) is lost, symptoms develop even when the subject is recumbent. Thirst,

shortness of breath, clouding or loss of consciousness, and sweating appear. The blood pressure, cardiac output, and central venous pressure are reduced.<sup>6,13</sup> The pulse usually becomes rapid and low in volume ("thin and thready"); however, in some patients, possibly in the "reactors" described above, bradycardia is observed. A redistribution of blood flow occurs as the result of adrenergic stimulation; flow to the heart, lungs, liver, and brain are favored at the expense of the skin, muscles, kidneys, and gastrointestinal tract. As a result of these hemodynamic changes, the skin, especially that of the extremities, becomes cold, clammy, and pale. Urine volume becomes reduced, and salt and water are conserved because of decreased renal blood flow and the actions of aldosterone and antidiuretic hormone.

When rapid blood loss exceeds 2000 to 2500 ml (40 to 50% of the blood volume), a severe state of shock ensues. Lactate acidosis resulting from inadequate tissue perfusion may be observed. At this stage, there is a significant risk that the shock will become irreversible, leading to death.

### Hematologic Findings

Immediately following hemorrhage, plasma volume and red cell mass are reduced in proportional amounts; consequently, there is no decrease in the VPRC (Fig. 19-2).<sup>1,3</sup> Over the next several days, the blood volume is restored by an influx of fluid containing electrolytes and protein. In recumbent subjects, most of the expansion of plasma volume occurs within the first 24 hours and is accounted for chiefly by movements of water and electrolytes. In ambulatory subjects, the plasma volume expansion is accomplished more slowly and is related primarily to mobilization of the extravascular albumin pool.<sup>1</sup> Because of the time required for these alterations in blood volume, the amount of blood loss tends to be underestimated by the degree of anemia, especially early in the course. The VPRC may not reach the minimum value until three or more days after the hemorrhage ceases (Fig. 19-2).

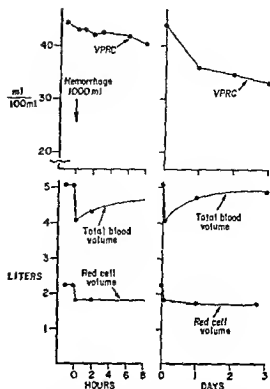

Fig. 19-2. The sequence of events during the first eight hours (left) and the first three days (right) following a single hemorrhage of 1.0 liter in a normal adult. The anemia develops slowly, and the VPRC does not reach the lowest values until about 72 hours after the hemorrhage. (Data from Ebert et al.<sup>13</sup> Figure from GR Lee<sup>14</sup> in *Text-Practice of Medicine*, Harper & Row, by permission.)

When first detected the anemia is normocytic and normochromic and there are few signs of erythrocyte regeneration. However, erythropoietin secretion is stimulated, and hyperplasia of marrow erythroid elements begins. This change may be evident on marrow examination within three to five days after hemorrhage.<sup>5</sup> Some increase in reticulocytes is usually perceptible within three to five days, and maximum values are reached at six to 11 days.<sup>11</sup> The degree of reticulocytosis is related to the magnitude of hemorrhage, but rarely exceeds 15%. The reticulocyte index (Chapter 20, page 731) may reach levels as high as 5.0 at 10 days.<sup>5</sup> Other signs of erythrocyte regeneration include polychromatophilia and macrocytosis, and the MCV may become transiently increased (Fig. 19-3). If the patient is seen for the first time during this stage, the findings may be mis-

Fig 19-3. Temporary increase in mean corpuscular volume associated with acute blood loss

taken for those of hemolytic anemia; however, signs of increased bilirubin production are conspicuously absent, unless bleeding has occurred into a body cavity or tissue space.

During or immediately after hemorrhage, the platelet count, the whole blood coagulation time, and the plasma fibrinogen level may be reduced.<sup>10</sup> These abnormalities usually are transient and their values return to normal within 15 minutes after bleeding ceases. Thereafter, the platelet count increases, often reaching levels above normal within an hour. Values as great as  $1000 \times 10^9/l$  may be observed. If severe shock develops, disseminated intravascular coagulation (Chapter 38) may occur.

Neutrophilic leukocytosis often follows hemorrhage, the leukocyte count becoming maximal at two to five hours. Typically, the leukocyte count is 10 to  $20 \times 10^9/l$  but counts as high as  $35 \times 10^9/l$  have been observed. The leukocytosis is explained by the effect of epinephrine on the mobilization of granulocytes from the marginal pool (Chapter 6) and by their release from the marrow granulocyte reserve.

## Diagnosis

The sudden onset of severe anemia, when not due to an obvious cause, should direct

suspicion to the gastrointestinal tract or, if the patient is a female, to the reproductive organs as sites of hemorrhage. Acute hemolytic anemia is much less common and is accompanied by hyperbilirubinemia, hemoglobinemia, and other signs (Chapter 20). As already mentioned, hemorrhage into one of the body cavities, or into a cyst, may be accompanied by hyperbilirubinemia arising from the breakdown and absorption of the blood.

## Management

During the hypovolemic phase, therapy should be directed toward restoration of the blood volume. When the situation is urgent, this can be accomplished with intravenous infusions of saline, albumin, plasma, or dextran solutions.<sup>7,8,9,12</sup> Whole blood represents the replacement therapy of choice,<sup>14</sup> and, if large amounts (more than 4 units per day) are required, fresh blood should be used. The risks and precautions related to transfusion therapy have been discussed in Chapter 11. Response to therapy must be gauged by observations of the pulse rate and blood pressure and the change in these parameters when the upright position is assumed. For reasons already discussed, the VPRC is of limited value as a guide to therapy. In critically ill

subjects and in complex clinical circumstances, it is often necessary to insert a catheter into a central vein or the pulmonary artery so that changes in pressure volume can be monitored as volume is replaced.

Once the emergency has been dealt with, remedial measures must be directed at the bleeding lesion, according to the nature of the underlying disease.

The anemia itself rarely requires specific therapy. If iron stores are adequate, the marrow is capable of regenerating the lost red cells and the rate of regeneration is not accelerated by administration of iron, folate, vitamin B<sub>12</sub>, or other "hematinic" substances. Schipdt found that, no matter how great the blood loss had been, the rate of erythrocyte regeneration was such that a level of about  $4.5 \times 10^{12}$  red cells per l was reached in about 33 days, the curve of regeneration rising more sharply in subjects having the more severe cases of anemia.<sup>11</sup> The red cell count was usually restored entirely to normal in four to six weeks, although the hemoglobin lagged behind, reaching normal only after six to eight weeks. In blood donors from whom an average of 555 ml of blood had been removed, an average drop in hemoglobin of 2.3 g/dl was observed, an amount which required 50 days to replace.<sup>4</sup>

After 10 to 14 days there should be no morphologic evidence of active red cell regeneration. The leukocyte count should be normal after three or four days. Continued bleeding is suggested by a maintained high level of reticulocytes. Persistent leukocytosis may result from the same cause or may be due to hemorrhage into body cavities or to complications. The latter, particularly infections, tend to delay the hematopoietic response.

## Congenital Dyserythropoietic Anemias (CDA)

Congenital dyserythropoietic anemias are rare familial disorders characterized by the association of refractory anemia with multinuclearity, karyorrhexis, and other bizarre nuclear abnormalities of erythrocyte precursors

in the bone marrow. Three types of CDA have been distinguished on morphologic grounds.<sup>27</sup> Type I is characterized by binuclearity, intranuclear chromatin bridges, and by changes in nuclear chromatin structure similar to those found in megaloblasts; type II, by normoblastic chromatin, bi- and multinuclearity and pluripolar mitosis; and type III, by pronounced multinuclearity (up to 12 nuclei per cell) in enormous (up to 50 to 60  $\mu$ m diameter) erythrocyte precursors ("gigantoblasts").

The degree of anemia is extremely variable. In some patients a thalassemia-like picture, evident in infancy, has been described. However, in about half the reported cases, the anemia has been of moderate degree, so that discovery was delayed until early adulthood.<sup>22</sup> In all three types, the morphologic and kinetic criteria of ineffective erythropoiesis have been present. Erythroid hyperplasia of the marrow is pronounced, but the reticulocyte count is not increased. Plasma iron transport is markedly increased, but red cell utilization is reduced. Often, indirect hyperbilirubinemia (as great as 3.5 to 4.0 mg/dl) and increased fecal urobilinogen excretion have been noted. Nevertheless, red cell survival has been normal or only slightly reduced. Endogenous carbon monoxide production has exceeded that which could be accounted for on the basis of destruction of circulating cells. Secondary hemochromatosis has been a common complication. The abnormal proliferation affects the erythrocyte line only; leukocytes, platelets, and their precursors remain normal.

### Type I

This is probably the rarest of the three types, having been reported in only six patients, including two pairs of siblings.<sup>28</sup> The anemia was mildly macrocytic, and anisocytosis and poikilocytosis were prominent. Binucleated cells, cells with incompletely separated or multilobulated nuclei, megaloblastic erythrocyte proliferation, and erythrophagocytosis were common findings. Additional morphologic abnormalities on electron

microscopy included uneven condensation and a spongy appearance of nuclear chromatin, loss of nuclear envelope, chromatin bridges between the nuclei of divided cells, and persistence of cytoplasmic microtubules.<sup>28</sup>

### Type II

This variety of CDA is also known as HEMPAS, an acronym derived from the initials of Hereditary Erythroblast Multi-nuclearity with Positive Acidified Serum test.<sup>23</sup> It has been reported in about 40 individuals and appears to be inherited as an autosomal recessive trait.<sup>22,23,21,29</sup> The principal clinical findings are normocytic anemia, variable jaundice, and hepatosplenomegaly. Anisocytosis and poikilocytosis are prominent. Multiple nucleoli are found in 10 to 40% of marrow normoblasts, especially those in the later stages of maturation. These cells appear to synthesize DNA at a markedly reduced rate.<sup>31</sup> However, in contrast to type I cases, no megaloblastic features are found. Phagocytosis of erythrocytes and normoblasts by reticulum cells, and Gaucher-like histiocytes have been observed in some patients.<sup>24</sup>

The erythrocytes resemble those in PNH (Chapter 29) in that they are unusually susceptible to hemolysis in most acidified normal sera and by anti-i and anti-I antibodies.<sup>23</sup> However, acid hemolysis does not occur in the patient's own serum. They also differ from PNH erythrocytes in that they do not hemolyze in the sugar-water test. These abnormalities imply a membrane defect, as yet undefined.<sup>23</sup> In one case studied by electron microscopy, the cytoplasmic membranes appeared to be doubled.<sup>31</sup> Additional red cell abnormalities include a pronounced increase in the activity of phosphoglucose isomerase, triosephosphate isomerase, and certain other glycolytic enzymes.<sup>29</sup>

### Type III

This was probably the first variety of CDA to be described.<sup>20</sup> It has been reported in

about 23 subjects in four families,<sup>22,26</sup> and the pattern of inheritance suggests autosomal dominant transmission.<sup>23</sup> The anemia has been normocytic or slightly macrocytic; a few very large erythrocytes have been seen on blood smear. As many as 30% of the erythrocyte precursors have been multinucleated. Remarkable variability in the amount of DNA per normoblast nucleus has been observed.<sup>26</sup> In one family, an abnormal hemoglobin was detected chromatographically in both affected and apparently healthy subjects.<sup>21</sup> In another patient, the erythrocytes were more readily agglutinated by anti-I antibodies than normal, but the reaction to the acidified serum test was negative.<sup>26</sup>

## The Anemia of Chronic Renal Insufficiency

Anemia accompanies chronic renal insufficiency with such regularity that it is as typical of the disorder as azotemia.<sup>52</sup> In the complex clinical settings associated with uremia, anemia may occur for many reasons. If the kidneys are infected or inflamed, the anemia of chronic disorders (Chapter 18) is likely to be observed. Iron-deficiency anemia (Chapter 17) may develop because of blood loss from the genitourinary or gastrointestinal tracts or into the hemodialysis apparatus.<sup>42,47,78</sup> Megaloblastic anemia due to folate deficiency also may occur in patients receiving periodic dialysis.<sup>62</sup> In certain types of renal disease, including the hemolytic-uremic syndrome and malignant hypertension, microangiopathic hemolytic anemia may be found (Chapter 28).

In addition, anemia occurs in uremia even in the absence of any of the above mechanisms. Failure of both the excretory and the erythropoietin-secreting functions of the kidney is implicated in its pathogenesis. Although red cell survival may be moderately shortened, the predominant kinetic characteristic is reduced red cell production. It is this "hypoproliferative"<sup>42</sup> anemia that is usually meant by the phrase "anemia of chronic renal insufficiency."

### Clinical Description

In most instances, the patient seeks medical attention because of symptoms related to the underlying renal disease, and anemia is an incidental finding. Occasionally, however, the renal symptoms are so subtle and slowly progressive that the patient's chief complaints are of pallor, exertional dyspnea, or other signs of the cardiovascular adjustment to anemia. When appropriate tests of renal function have not been performed, hematologic consultation may be requested for the diagnosis of what appears to be a mysterious, normocytic normochromic anemia.

A very rough correlation has been observed between the degree of anemia and the degree of renal impairment, as judged by the blood urea nitrogen (BUN) or creatinine level<sup>53,55,67,93</sup> (Fig 19-4). A significant hyperbolic correlation also was observed between glomerular filtration rate (GFR) and the blood hemoglobin level.<sup>75</sup> Anemia developed only when GFR was reduced to less than 30% of normal, a level corresponding to an increase in plasma creatinine to about

2 to 4 mg/dl. Pronounced anemia was observed when the GFR fell below 20 ml/minute/1.73 m<sup>2</sup>. The nature of the renal disease leading to uremia has little effect on the development of anemia; however, the degree of anemia may be somewhat less in patients with hypertension<sup>64</sup> and considerably less in patients with polycystic disease.<sup>49</sup> In the Salt Lake Veterans Hospital Hemodialysis Unit, the mean VPRC in nine subjects with polycystic disease was 0.37 l/l as compared with 0.23 l/l in 27 subjects with other types of chronic renal failure.<sup>95</sup>

### Laboratory Findings

The anemia may progress as renal failure worsens, but ultimately in most patients the VPRC becomes stabilized between 0.15 and 0.30 l/l and does not fall to lower levels unless complications develop.<sup>42</sup> Since regulation of body water and electrolyte balance is impaired in renal disease, both hydremia and dehydration are common. Thus, the apparent degree of anemia may be exaggerated or minimized by alterations in plasma volume.

Fig 19-4. Relation between blood urea nitrogen (BUN) and blood hemoglobin concentration (From Kaye,<sup>67</sup> courtesy of author and Journal of Laboratory and Clinical Medicine)

The erythrocytes usually are normocytic and normochromic,<sup>46, 53, 67, 70, 86</sup> but slight macrocytosis occasionally has been observed.<sup>70</sup> Often the red cells appear normal or nearly so on blood smear; characteristically, little variation in size or shape is seen, and cells that are polychromatophilic or stippled are unusual. Occasionally, however, "burr" cells (Chapter 13) may be observed along with some triangular, helmet-shaped or fragmented cells. The reticulocyte count often is within normal limits,<sup>46</sup> but may be moderately increased.<sup>53, 68, 70</sup> In one study, reticulocytes were normal when the BUN was less than 130 mg/dl, but, at higher BUN levels, their number often was increased.<sup>89</sup> The highest values (average 6%) were observed when the BUN was between 300 and 350 mg/dl.

The leukocyte count often is normal, but slight neutrophilic leukocytosis may be observed. In one series, the leukocyte count averaged  $10.7 \times 10^9/l$ .<sup>46</sup> The platelet count was either normal or slightly increased.<sup>46</sup> However, platelet function may be severely impaired, resulting in defective hemostasis<sup>94, 90</sup> (Chapter 35).

The bone marrow tends to be moderately hypercellular, and erythroid hyperplasia may be observed. The average M:E ratio was found to be 2.5:1 in one study.<sup>46</sup> Erythrocyte maturation appeared morphologically normal. In some instances, especially when the renal failure is relatively acute, hypoplasia of erythroid elements may be found.<sup>78, 85, 88</sup>

Measures of bile pigment production tend to give normal or somewhat increased values. The serum bilirubin was within normal limits in all of the 26 patients in one series.<sup>70</sup> However, the hemolytic index, a measure of urobilinogen excretion in relation to total circulating hemoglobin (Chapter 5, page 217), was increased in eight of 21 patients in two studies.<sup>67, 70</sup> In only three of these patients did the hemolytic index exceed 40 (normal, 11 to 21).

Values for serum iron vary considerably in renal disease.<sup>53, 70</sup> As a general rule, the value is normal when renal impairment is mild. With more severe disease, some investigators

have observed a fall in serum iron levels,<sup>67</sup> whereas others have found hyperferremia.<sup>53, 58</sup> This lack of agreement may be partially explained by complicating factors. For example, if iron overload has been induced by multiple transfusions, hyperferremia is to be expected.<sup>54</sup> On the other hand, if the renal disease is complicated by blood loss or by inflammation or infection, hypoferremia results. Whether there is a characteristic disturbance of serum iron concentration in "uncomplicated" uremia remains to be determined. One group of investigators found gastrointestinal absorption of iron, measured with the total body counter, to be reduced in patients with chronic renal failure.<sup>43</sup> Others, using the less satisfactory double isotope method, found iron absorption to be related to disturbances in iron balance and to be unrelated to degree of anemia, rate of erythropoiesis, or degree of azotemia.<sup>87</sup>

Free erythrocyte protoporphyrin may be normal or moderately increased.<sup>70</sup> Erythrocyte lactate dehydrogenase (LDH) is within normal limits.<sup>71</sup>

### Kinetic Studies and Pathogenesis

The major pathogenetic factor in the anemia of uremia is failure of the bone marrow to produce adequate numbers of red blood cells. When anemia is severe, ferrokinetic studies typically demonstrate a normal plasma iron transport rate, but red cell iron utilization and erythrocyte iron turnover are reduced (Table 19-2).<sup>42, 70, 71</sup> With milder degrees of anemia, ferrokinetic measurements tend to be near normal (Table 19-2).

It must be emphasized, however, that in anemic patients such "normal" values indicate an insufficient marrow response to the stimulus of anemia.

The defect in erythropoiesis is at least partially explained by failure of the renal erythropoietin-secreting mechanism (Chapter 4, page 180). In the great majority of patients with renal disease, plasma erythropoietin is not detectable even when anemia is severe.<sup>45, 56, 79, 82</sup> It is probable that, in man, extrarenal sources of erythropoietin<sup>81, 83</sup> ac-

count for the maintenance of a steady, but subnormal rate of red cell production in uremic and anephric subjects. The extrarenal erythropoietin secretion does not, however, appear to increase sufficiently in response to anemia to compensate for deficiencies at the renal source.

In addition to erythropoietin deficiency, other factors may depress erythropoiesis in patients with uremia. Evidence has been presented for the presence of an erythropoietin-inhibiting substance, possibly of renal origin, in the plasma of some patients with chronic renal failure.<sup>59,79</sup> Moreover, the uremic state appears to inhibit the response to exogenously administered erythropoietin.<sup>44,92</sup> Finally, the rate of erythropoiesis has been found to improve in patients treated with dialysis, even though plasma erythropoietin levels have remained unchanged.<sup>56,68,72</sup>

A second pathogenetic factor is erythrocyte survival, which, although often within normal limits, may be slightly to moderately reduced. In only 20 of 106 patients studied with the <sup>51</sup>Cr technique by five different groups of investigators<sup>52,67,68,89,93</sup> was the erythrocyte life span clearly reduced. As determined by the Ashby method, erythrocyte half-survival time averaged 44 days and ranged from 21 to 68 days in 10 uremic patients (normal 52 to 68 days).<sup>70</sup> When measured with DF<sup>32</sup>P, erythrocyte survival averaged 66 days and ranged from 30 to 100 (normal 120 days) in 13 patients whose azotemia was controlled by dialysis.<sup>56</sup> The degree to which red cell survival is shortened has been alleged to be related to the degree of azotemia,<sup>42</sup> but others have found this relationship to be unimpressive.<sup>55</sup>

Cross-transfusion studies usually have indicated that the hemolytic factor, when present, is extracorporeal. Survival of normal cells transfused into patients was shortened, whereas the patient's cells survived normally in normal recipients.<sup>52,67,70</sup> Less commonly, shortened survival of the patient's cells has been observed even in normal subjects.<sup>67</sup> In some patients, splenic sequestration of red cells may be prominent.<sup>63</sup>

The mechanisms of increased erythrocyte

destruction have not been clearly delineated. The reaction to the Coombs' test is negative.<sup>70</sup> Erythrocyte osmotic fragility usually is within normal limits.<sup>52,70</sup> Mechanical fragility is normal<sup>70</sup> or slightly increased.<sup>52</sup> The autohemolysis test has been found to give normal values by some<sup>52</sup> and increased values by others.<sup>60</sup>

A number of potentially toxic substances accumulate in uremia, and it is conceivable that one or more of them may interfere with erythrocyte function, resulting in premature cell death. As yet, however, neither a specific toxin nor impairment of a single metabolic function has been clearly implicated in the reduced red cell survival. Welt and his co-workers found that red cell sodium concentration was increased in about 25% of patients with uremia.<sup>94</sup> In the patients with this abnormality, erythrocyte ATPase activity and active sodium efflux were found to be reduced. These observations suggested that a defect in membrane ion transport might explain reduced red cell survival. In contrast, however, Lichtman and Miller, in 20 uremic subjects, could detect no impairment of ATPase activity or of ATP utilization.<sup>69</sup>

Evidence of impaired erythrocyte glycolysis in uremia has been reported<sup>71</sup>; however, most studies have found the overall glycolytic rate to be increased,<sup>69,83</sup> probably because of the elevation in plasma inorganic phosphorus.<sup>69</sup> The increase in glycolytic rate probably accounts for the observed increase in red cell ATP levels.<sup>69</sup> Hemoglobin oxygen affinity is reduced,<sup>76</sup> presumably because of increased erythrocyte ATP and 2,3 DPG levels. Such abnormalities would not be expected to cause reduced red cell survival.

Evidence has also been presented that shortened red cell survival in some uremic patients results from impaired function of the hexosemonophosphate (HMP) shunt. This abnormality was induced by accumulation of a toxic, nondialyzable substance, possibly chloramine derived from chlorinated tap water use in dialysis media.<sup>66</sup> In these studies, shortened erythrocyte survival correlated well with the results of the ascorbate-cyanide screening test (page 736), which was abnor-

mal in 43 of 100 uremic patients. These patients developed severe, Heinz body hemolytic anemia if given primaquine, and Heinz bodies were also observed in splenectomized, nephrectomized patients not given this drug. Thus, the hemolytic pattern in these patients resembled that observed in G-6-PD deficiency (Chapter 23). Such an HMP shunt abnormality also may explain previously observed abnormalities in red cell glutathione content and stability in uremia.<sup>91</sup>

# Management and Course

In patients with mild renal failure and few symptoms, no therapy is required for the anemia. Eventually most patients with progressive disease require one of two major therapeutic regimens, namely, regular maintenance hemodialysis or renal homotransplantation. These procedures have completely changed the prognosis in uremia. The management and response of the anemia differ, depending on which of these two modes of therapy is employed.

Although maintenance hemodialysis<sup>13,47,48,49,56,61,68,78,96</sup> is an effective means of controlling most of the symptoms and biochemical manifestations of renal failure, anemia continues to be a problem in many patients on this regimen. In such patients, it appears preferable to give no blood transfusions unless symptoms due to anemia or blood loss occur.<sup>48,49,61,95</sup> Usually the VPRC stabilizes at a level above 0.15 l/l, and most patients tolerate this degree of anemia remarkably well. Even lower levels have been tolerated by young patients who have no associated disorders.<sup>78</sup> After one to 10 months or more of treatment, modest reduction in the degree of anemia or in transfusion requirements has been observed.<sup>48,56,61,78</sup> In one study of 36 patients, the VPRC rose from an average of 0.21 l/l (range 0.12 to 0.29) to 0.27 (range 0.16 to 0.48) on hemodialysis.<sup>48</sup> The improvement results chiefly from an increase in red cell production, even though erythropoietin levels do not increase.<sup>56,68,72</sup> The use of routine transfusion to maintain the VPRC at levels around 0.25 l/l has been

considerably less satisfactory. With such a regimen, an average of 3.1 units of blood per month (range 0.5 to 5.0 units/month) was required<sup>91</sup> as compared with 0.34 units per month<sup>19</sup> or less<sup>96</sup> when given only after symptoms developed. Not only is the risk of hepatitis and iron overload<sup>94</sup> significantly increased by routine transfusion, but erythropoiesis is depressed.<sup>61,82</sup>

When transfusions are withheld, iron deficiency is a common complication of hemodialysis, affecting perhaps half or more of the patients.<sup>47,78,96</sup> Loss of blood in the dialysis apparatus is the usual cause.<sup>48,49,78</sup> Detection of iron deficiency may be difficult in this situation because the usual morphologic criteria may be absent<sup>96</sup> and some<sup>49</sup> but not all<sup>47</sup> investigators have found even the plasma iron levels to be misleading. Various approaches to the treatment and prevention of the iron deficiency have been employed. It seems reasonable to administer oral iron prophylactically to all hemodialysis patients. The dose should be increased to tolerance, eg, as much as 600 mg of elemental iron per day (3 ferrous sulfate tablets three times daily) because of possibly defective intestinal absorption.<sup>43</sup> Parenteral iron also has been used, eg, 100 mg of iron as Imferon given intravenously after each dialysis.<sup>47,48,78</sup> This procedure effectively relieves the iron deficiency, but if continued indefinitely results in significant hepatic iron overload.<sup>49</sup> Alternatively, single or multiple injections totaling 1.0 g of iron have been given only to patients with clearly subnormal plasma iron values.<sup>78,96</sup> In 10 patients so treated, hemoglobin increases of 2.4 g/dl were observed over a four- to six-week period.<sup>96</sup>

Androgens may be useful adjuncts to therapy in patients who continue to develop symptoms of anemia and to require blood transfusion even when iron stores are adequate.<sup>50,87</sup> Testosterone enanthate, given intramuscularly, has been used in doses of 400 to 600 mg/week. A mean increase in VPRC of 0.056 l/l was observed with this treatment,<sup>87</sup> eliminating the need for transfusion.<sup>50,87</sup> Androgens also appear to increase erythrocyte 2,3 DPG in patients with

renal disease, a change which facilitates oxygen delivery to tissues.<sup>84</sup>

In one study, four patients who had a continuing need for transfusions while receiving hemodialysis treatment were found to have excessive splenic sequestration of erythrocytes. Marked improvement in red cell survival and disappearance of the transfusion requirement followed splenectomy.<sup>63</sup>

If a renal homograft is successful, both erythropoietic and excretory functions may

return.<sup>41,51,65,73,80</sup> Normal levels of erythropoietin often can be detected in plasma following a graft.<sup>41,51,80</sup> When the graft persists for two or more months, it is common to observe a reticulocyte response and an increase in VPRC (Fig. 19-5). Normal and even supra-normal<sup>65</sup> VPRC values ultimately may be achieved, but the hematologic response often is delayed until immunosuppressive measures can be reduced (Fig. 19-5). In one series, 80% of over 100 patients demonstrated

Fig 19-5. The response of the anemia of renal disease to renal transplantation (From Abbrecht and Greene,<sup>41</sup> courtesy of authors and *Annals of Internal Medicine*)

an increase in blood hemoglobin following renal homograft.<sup>65</sup> Failure to respond could usually be explained on the basis of hemorrhage, vigorous immunosuppression, or graft rejection. Interestingly, the rejection phenomenon often has been accompanied by increased erythropoietin levels.<sup>41 80</sup>

## Anemia in Cirrhosis and Other Liver Diseases

Anemia is a frequent manifestation of liver disease. It is particularly characteristic of Laennec's cirrhosis, and much of the information to follow has been derived from the study of patients with that disorder. In addition, however, changes in the structural characteristics of the red cells, reduction in red cell survival time, and even mild anemia have been observed in association with such entities as biliary cirrhosis,<sup>110</sup> hemochromatosis,<sup>116</sup> postnecrotic cirrhosis,<sup>116</sup> and acute hepatitis.<sup>121</sup> These studies will be cited where relevant.

Many etiologic factors have been implicated in the anemia associated with liver disease. Thus, *folate deficiency* may be present, especially in alcoholics (Chapter 14, page 578). Furthermore, even in the absence of liver disease, alcohol has been shown to exert a direct depressive effect on the bone marrow (Chapter 18, page 686). Iron deficiency also may develop in patients with liver disease as a result of blood loss, chiefly from the upper

gastrointestinal tract, but also from the nose, from hemorrhoids, and from menorrhagia because of a frequently associated disturbance of hemostasis (Chapter 38). In various series, blood loss occurred in from 24 to 70% of patients with alcoholic cirrhosis.<sup>116</sup> In addition, however, anemia may be found in association with liver disease in the absence of any of the above complicating factors. Although much remains to be learned regarding the pathogenesis of such "uncomplicated" anemia, it appears to result from a combination of hypervolemia, shortened red cell survival, and impaired ability of the marrow to respond to the anemia.

### Prevalence and Severity

Approximately 75% of patients with chronic liver disease are found to have anemia as defined by a reduction in the VPRC or hemoglobin level.<sup>101,116,122,123,125</sup> The whole blood volume, however, averages about 15% greater than normal (Table 19-3), and this hemodilution tends to exaggerate the anemia.<sup>116,118</sup> Thus, some patients may have a reduced VPRC even though the circulating red cell mass is normal. In one series, the incidence of anemia (VPRC less than 0.40 l/l) was 70%, but the circulating red cell mass was reduced in only 40% of the patients.<sup>122</sup> The magnitude of the hypervolemia in Laennec's cirrhosis appears to be related to the degree of portal hypertension, but not to the

Table 19-3. Changes in Blood Volume in Patients with Cirrhosis<sup>118</sup>

Measurement	Normal Subjects	Patients with Cirrhosis	
		Without Ascites	With Ascites
VPRC (l/l)	0.42	0.35	0.34
Red cell mass (ml/kg)	23	20	19
Plasma volume (ml/kg)	42	57	55
Whole blood volume (ml/kg)	65	74	74

Values are means of 24 normal subjects, 63 patients with cirrhosis and no ascites, and 34 patients with cirrhosis and ascites. In all groups there were about twice as many men as women.

presence or absence of ascites (Table 19-3).<sup>118</sup>

The degree of anemia is rarely severe in the absence of complications. In a series of 35 patients with alcoholic cirrhosis, the hemoglobin level averaged 12.3 g/dl, although it ranged from 6.8 to 15.8 g/dl.<sup>116</sup> Similar values have been reported by others.<sup>122,125</sup>

### Hematologic Findings

In its "uncomplicated" form, the anemia of liver disease probably is normocytic and normochromic. However, there are few observations on which such a judgment can be made, since, in most reported series, a population of patients with "uncomplicated" anemia has not been clearly identified. Occasionally the anemia is mildly macrocytic, but it is rare for the MCV to exceed 115 fl in the absence of megaloblastic changes in the bone marrow (Chapter 14). When there is complicating iron deficiency, hypochromia may be observed, but microcytosis is unusual.<sup>116</sup>

When true macrocytosis is found in patients with liver disease, it probably results either from complicating folate deficiency or from stimulated erythropoiesis.<sup>115</sup> The reported incidence of an increased MCV in patients with liver disease has varied from 33 to 65%.<sup>101,112,116,117</sup> Even more common is so-called "thin" macrocytosis, which may be defined as an increase in mean cell diameter with a normal mean cell volume (Chapter 14, page 567). In one study of 222 patients with various kinds of liver disease, an increased mean cell diameter was found in 137 (62%).<sup>102</sup> The cases were classified into three groups: "thin" macrocytosis (81 patients), "target" macrocytosis (39 patients), and "thick" macrocytosis (17 patients). The MCV was increased only in the last group.

The reticulocyte count often is increased. In a study of 16 patients, the maximum count averaged 8.6% and ranged from 2.3 to 24.6%.<sup>112</sup> The reticulocytosis can be suppressed by alcohol ingestion; therefore, if alcohol intake has continued until the patient is first seen, the reticulocyte count probably

will be low. Then, upon withdrawal of alcohol, an increase will be observed, with the maximum value occurring on about the seventh day.<sup>112</sup>

Mild thrombocytopenia is found in about half the patients with cirrhosis, but values less than  $50 \times 10^9/l$  are uncommon.<sup>101,122</sup> A variety of leukocyte abnormalities may be observed; in a study of 25 patients, 16 had lymphopenia, four had neutropenia, and 12 had neutrophilia.<sup>101</sup> Severe pancytopenia associated with splenomegaly in liver disease (Banti's syndrome) is discussed in Chapter 45.

Bone marrow cellularity is normal or increased.<sup>101,116,117</sup> Often erythroid hyperplasia, with a reduced M:E ratio, is observed. Red cell precursors at times have been described as "macronormoblasts," a term which implies that their size is increased but that their nuclear chromatin structure is normal.<sup>101,117,120</sup> In as many as 20% of the subjects, however, frank megaloblastosis may be present (Chapter 14, page 578).

### Erythrokinetics and Pathogenesis

Red cell survival tends to be moderately shortened in patients with alcoholic liver disease. When measured with the <sup>51</sup>Cr method (Chapter 5, page 197), erythrocyte survival was subnormal ( $t_{1/2}$  Cr less than 24 days) in 48 of 68 patients (70%) in four different studies.<sup>113,116,121,122</sup> The average  $t_{1/2}$  Cr in these patients was 20 days; in only 14 of them was the  $t_{1/2}$  Cr less than 16 days. Shorter survival was observed in a more anemic population of cirrhotic patients (mean hemoglobin 9.3 g/dl).<sup>112</sup> In them, the average  $t_{1/2}$  determined by the Ashby method (page 197) was 22.7 days and the range five to 49 days (normal, 52 to 68 days). The disappearance pattern was curvilinear, indicating random destruction. The rate of red cell disappearance correlated well with the degree of anemia. Erythrocyte survival is particularly likely to be reduced in patients with predominant indirect bilirubinemia, ie, when the indirect fraction is greater than 2.5 mg/dl and constitutes more than 70% of the

total.<sup>108</sup> Erythrocyte survival also has been found to be significantly shortened in patients with biliary cirrhosis,<sup>110</sup> obstructive jaundice, and infectious hepatitis,<sup>108,121</sup> even in the absence of anemia.

The reasons for the decreased red cell life span in liver disease have not been elucidated fully. Cross transfusion studies have demonstrated improved survival when patient cells were transfused to normal recipients, suggesting that the hemolytic factor is extracorporeal.<sup>111</sup> Jandl and associates suggested that sequestration and destruction of red cells in the often enlarged spleen plays a prominent role.<sup>112</sup> It is true that erythrocyte survival is found to be significantly shorter in patients with splenomegaly than in those without.<sup>116</sup> Furthermore, with the <sup>51</sup>Cr technique, excessive splenic sequestration has been demonstrated in some patients<sup>108,110,112,127</sup>; but in the majority, splenic uptake was normal even though erythrocyte survival was reduced.<sup>116</sup> In a few patients, but not all, splenectomy has been followed by correction of the hemolytic process.<sup>101,111,122</sup>

Characteristic alterations in red cell membrane lipids are found in patients with hepatitis, cirrhosis, and obstructive jaundice<sup>109,106,119,123</sup> (Fig. 19-6). In the usual

case, there is a 25 to 50% increase in both cholesterol and lecithin in the membrane. These changes result in an increased cell surface area, leading to the characteristic "thin macrocyte" or target cell. There is no good evidence, however, that such abnormalities result in reduced cell survival. In contrast, in a few patients with severe hepatocellular disease, an accumulation of membrane cholesterol occurs without a corresponding increase in lecithin. This is associated with the formation of so-called "spur cells," erythrocytes which are covered with spike-like projections and which probably are morphologically indistinguishable from the acanthocytes seen in abetalipoproteinemia (page 762).<sup>106,121,126</sup> The appearance of spur cells is accompanied by pronounced shortening of erythrocyte survival, possibly because the distorted cells become trapped in the reticuloendothelial system. The alteration in red cell lipids in liver disease is not fully understood, but at least three factors have been implicated: (1) reduced LCAT activity (Chapter 3), (2) retention of bile salts, and (3) increase in the plasma free cholesterol to phospholipid ratio.<sup>106</sup> Spur-cell hemolytic anemia can be induced in vivo by administration of lithocholic acid,<sup>107</sup> but a pathogenetic relation between this bile-acid deriv-

Fig. 19-6 Erythrocyte membrane lipids in liver disease. Normal values are shown in the lower left-hand corner. In patients with target cells the degree of increase in cholesterol correlates well with that in phospholipids. In "spur cell" anemia, only cholesterol is increased. (From Cooper and Jandl,<sup>104</sup> courtesy of the authors and Journal of Clinical Investigation.)

ative and naturally occurring spur-cell anemia has not been established.

Zieve distinguished a special group of patients with alcoholic liver disease and shortened red cell survival.<sup>129</sup> They had mild impairment of hepatic function, and fatty infiltration was the predominant histologic finding. Plasma triglycerides were markedly increased. Both the shortened  $t_{1/2}$  and the liver disease tended to be transient. Recovery was spontaneous, but recurrence on exposure to alcohol was not unusual. Whether this syndrome represents a distinct pathophysiologic entity or a collection of findings occurring together by chance remains uncertain. In particular, there is no direct evidence that the triglyceridemia induces hemolysis.<sup>123</sup> Furthermore, red cell lipids in patients with "Zieve's syndrome" are no different than those found in other cirrhotic patients.<sup>105</sup>

In addition to the shortened erythrocyte survival, some studies have suggested that in patients with liver disease the marrow response to the anemia is inadequate. For example, plasma iron turnover, red cell iron utilization, and erythrocyte iron turnover were normal or reduced in the majority of patients in one series.<sup>116</sup> In another study, however, these parameters were increased two- to threefold<sup>103</sup> (Table 19-2). The presence or absence of complications may explain such discrepancies. Alcohol, in particular, will depress erythropoiesis, and if the patient is studied before the effects of alcohol ingestion have subsided, marrow function will appear to be depressed.

Another possible explanation has been advanced for impaired erythropoiesis in liver disease. It is possible that one of the functions of the normal liver is the synthesis of an erythropoietin precursor that can be activated by interaction with a renal enzyme (Chapter 4, page 181). The erythropoietin response to hypoxia was found to be markedly impaired in hepatectomized or partially hepatectomized rats as compared to sham-operated controls.<sup>114</sup> Additional evidence for a hepatic erythropoietic factor is found in certain patients who develop erythrocytosis with hepatic carcinoma.<sup>109</sup> It is possible, therefore,

that a diseased liver makes inadequate amounts of this precursor. As yet, there is no direct proof for this hypothesis.

## Anemias Associated with Endocrine Disorders

Anemia commonly accompanies disorders affecting the thyroid gland, adrenal glands, gonads, or pituitary gland. In general the anemia is mild to moderate in degree and produces no symptoms. In fact, the amount of circulating hemoglobin may be entirely appropriate to the needs of the organism because the metabolic disturbance often results in reduced oxygen requirements. In most patients, these endocrine disorders begin insidiously and the early symptoms are nonspecific and include fatigue. Consequently, when the initial investigation detects a reduced hemoglobin level, the symptoms may be ascribed to the anemia and the diagnostic studies may then be directed toward the hematopoietic system. Few morphologic abnormalities will be observed and none is specific. Unless the clinician suspects endocrine disease, the diagnosis may be overlooked.

### Hypothyroidism

In various reported series, anemia has been observed in 21 to 60% of patients with hypothyroidism.<sup>118</sup> Three morphologic types of anemia have been described in these patients.<sup>145,148,174,195</sup> The relative incidence of the three types differed considerably in two large series reported since 1960 (Table 19-4). The reasons for the differences are not clear, but they may have been related to factors not directly concerned with the thyroid disease as well as to its degree and duration (see below). When *hypochromic, microcytic anemia* was found in association with myxedema it was due to iron deficiency.<sup>145,182,198</sup> It responded to iron therapy even if thyroid hormone was not administered, and was not relieved by hormone therapy if iron was withheld. Iron deficiency occurs in association with myxedema partly because menor-

Fig 19-7. Photographs of a girl of 15 years with "refractory" anemia, before and four months after therapy with desiccated thyroid. Note the pale, puffy, pasty appearance before therapy.

rhagia is a frequent manifestation of the illness,<sup>169</sup> and partly also, perhaps, because the achlorhydria found in myxedema subjects<sup>198</sup> may lead to impaired absorption of food iron (Chapter 4, page 156). Distinctly *macrocytic anemia* usually results from complicating deficiency of vitamin B<sub>12</sub><sup>193</sup> or folate.<sup>174</sup> The increased incidence of pernicious anemia in thyroid disease possibly is the result of an autoimmune mechanism, as discussed in Chapter 15 (page 606). Folate deficiency may

have developed because of an inadequate diet, but this could not be established with certainty.<sup>174</sup>

If the patients with iron, folate, or vitamin B<sub>12</sub> deficiency are excluded, there remains a significant population of hypothyroid patients with anemia. This type of anemia constitutes the so-called "uncomplicated anemia of hypothyroidism,"<sup>143,174,198</sup> and is a manifestation of the hormone deficiency itself. The anemia usually is mild, the VPRC rarely falling below 0.35 l/l. However, the plasma volume often is decreased,<sup>167,188,199</sup> a change which tends to minimize the reduction in VPRC. The degree of anemia is related to both the severity and duration of the hypothyroidism.<sup>196</sup> It was observed that the VPRC continued to fall for as long as six months after thyroidectomy in previously euthyroid subjects, even though the basal metabolic rate remained at a stable, reduced level. In man, the "uncomplicated" anemia usually is normocytic and normochromic, but may be slightly macrocytic.<sup>148,174,198</sup> It is macrocytic in rabbits<sup>180</sup> and rats<sup>170,193</sup> and normocytic in dogs.<sup>175</sup> Anisocytosis, poikilocytosis, or other red cell morphologic abnor-

Table 19-4. The Incidence of Various Types of Anemia in Patients with Myxedema from Two Different Studies

Type of Anemia	Sheffield, England <sup>198</sup>	University of Virginia <sup>148</sup>
Normocytic normochromic	4%	26%
Hypochromic, microcytic	14%	3%
Macrocytic	13%	14%
All anemias	31%	43%

malities are not impressive, and usually the leukocyte and platelet counts are within the normal range, although both may be slightly reduced.<sup>196</sup> The bone marrow may be mildly hypoplastic, but there is no significant alteration in the M:E ratio.<sup>142,178</sup>

From a kinetic viewpoint, the anemia of myxedema seems to be entirely explained by reduced red cell production. With one exception,<sup>147</sup> reported studies have indicated that erythrocyte survival is normal or even slightly prolonged in man<sup>179,184,191,198</sup> and in dogs,<sup>149</sup> but plasma iron transport and erythrocyte iron turnover rates are reduced, indicating *subnormal red cell production*<sup>58,175,179</sup> (Table 19-2).

Bornford was the first to suggest that the anemia of myxedema was "adaptive" in nature, i.e., a physiologic adjustment to the reduced needs of the organism for oxygen.<sup>145</sup> Since that time, this hypothesis has become even more tenable because of what has been learned about the erythropoietin-secreting mechanism and its relation to tissue oxygen tension (Chapter 4). There also is experimental evidence consistent with it. For example, the marrow of the isolated, hind limb of the dog exhibits an erythropoietic response to perfusion with erythropoietin, but not to L-triiodothyronine (T<sub>3</sub>),<sup>162</sup> an observation which suggests that the role of the latter hormone is indirect. Furthermore, administration of 2,4 dinitrophenol, a drug which increases oxygen consumption without improving thyroid function, causes an increase in red cell mass in hypothyroid patients<sup>188</sup> and in thyroidectomized rats.<sup>160</sup> Finally, hyperoxia can inhibit the erythropoietic response to T<sub>3</sub>.<sup>164</sup> However, the observation that non-calorigenic D-isomer of triiodothyronine can stimulate erythropoiesis without alternating oxygen consumption has been cited as evidence for a hormonal effect that is not oxygen dependent.<sup>157,175,186</sup>

The response of the anemia of hypothyroidism to thyroid hormone is sluggish. Characteristically, there is no distinct reticulocytosis, and the VPRC returns to normal only gradually over about a six-month period (range three to 12 months).<sup>145,148,198</sup>

## Hyperthyroidism

The circulating red cell mass usually is increased in patients with hyperthyroidism<sup>167,185</sup>; however, the VPRC most often remains within normal limits because the plasma volume also increases. In general, the rate of erythropoiesis is increased both in hyperthyroid patients<sup>156</sup> and in experimental animals.<sup>200</sup> Erythrocyte 2,3 diphosphoglycerate (2,3 DPG) is increased, resulting in reduced oxygen affinity,<sup>187,194</sup> changes which are appropriate to increased tissue oxygen utilization (Chapter 3).

Anemia is uncommon in hyperthyroidism; however, in one study, among 50 patients with hyperthyroidism, four women were found with moderately severe anemia (VPRC, 0.27 to 0.30 l/l) for which no cause could be found other than the metabolic disorder.<sup>190</sup> Furthermore, the anemia was corrected when the hyperthyroidism was treated. In the anemic patients, the hyperthyroidism was of unusual severity and prolonged duration. Mild anisocytosis and poikilocytosis were present and slight hypochromia was apparent in three of the four. Impaired iron utilization was found on ferrokinetic study, suggesting that erythropoiesis was ineffective.

## Addison's Disease

In 28 patients with untreated Addison's disease, the average blood hemoglobin level was 13.2 g/dl and the range was 9.4 to 18 g/dl.<sup>143</sup> The red cells were normocytic and normochromic. Shortly after hormonal replacement therapy was begun, various measures of red cell concentration fell about 20%—the average hemoglobin from 13.7 to 10.7 g/dl and the VPRC from 0.416 to 0.325 l/l. It was concluded that the red cell mass is reduced in Addison's disease, but that the change is partially obscured by the dehydration that usually accompanies the condition. Treatment corrected the dehydration and restored the plasma volume, thereby making apparent the true degree of anemia. Later in the course,

reticulocytosis and return to normal hemoglobin levels were observed.

Following adrenalectomy in rats maintained on saline solution, a mild anemia develops.<sup>151,171,199</sup> The blood hemoglobin drops about 1.5 g/dl in three weeks. The anemia is corrected by administration of adrenal corticoids.

### Hypogonadism

After the age of puberty, values for the VPRC, blood hemoglobin concentration, and red cell count average about 10 to 13% higher in men than in women (see appendix A). In eunuchoid or castrated men, the values for these measures fall to within the normal female range.<sup>141,185</sup> Urinary erythropoietin levels in normal men are about three times those found in women.<sup>110</sup>

The differences between the sexes are accounted for chiefly by the stimulating effect of androgens on erythropoiesis. In addition, some observations suggest that estrogens exert a suppressive effect. Thus, castration of male rats is followed by a decrease in hemoglobin, whereas castration of female rats brings about an increase.<sup>152,168,195</sup> The administration of androgens to castrated males corrects the anemia. Androgens can also stimulate erythropoiesis in normal subjects. In normal men, testosterone enanthate induced an average increase in the total red cell mass from 1.7 to 2.3 liters.<sup>165</sup> The increase in VPRC was of smaller magnitude, from 0.456 to 0.494 l/l, probably because the plasma volume also increased. Androgens act by increasing renal synthesis of erythropoietin (or the renal erythropoietic factor).<sup>141,172</sup> Estrogens produce anemia when given in large amounts to rats,<sup>158,189</sup> possibly by suppressing hepatic synthesis of the serum substrate for erythropoietin<sup>172</sup> (Chapter 4).

### Hypopituitarism

Moderately severe, nonprogressive anemia is a well-recognized feature of pituitary insufficiency, regardless of cause. In an extensive review of 595 reported cases of Sim-

mond's disease, published in 1942, the average blood hemoglobin concentration was found to be 67 "percent of normal" (approximately 10 g/dl),<sup>159</sup> and the range was 21 to 103 "percent" (3 to 16 g/dl). Similar values were found in patients whose hypopituitarism arose from neoplasms.<sup>154,173</sup> Anemia may also be found in prepubertal pituitary dwarfs<sup>177</sup>; however, the degree of reduction of circulation red cell volume may be obscured by contraction of the plasma volume.<sup>192</sup>

The anemia usually is normocytic and normochromic, and the red cells appear morphologically normal. In some patients, slight hypochromia or macrocytosis has been observed<sup>151,197</sup>; however, complicating deficiencies of iron or folate were not excluded. Kinetic studies have demonstrated reduced red cell production.<sup>155,177</sup>

The anemia of hypopituitarism probably results from deficiencies of the hormones of target glands controlled by the pituitary, especially the thyroid and adrenal hormones, but also androgens. In addition, lack of other pituitary factors, such as growth hormone,<sup>153,163,168,177,192</sup> prolactin,<sup>178</sup> or other poorly characterized pituitary principles<sup>183</sup> may be of importance. The interrelations of these various hormones have been studied in experimental animals, especially the rat. In this species, hypophysectomy results in a moderately severe, slightly hypochromic and microcytic anemia<sup>144,153</sup> that is associated with a pronounced decrease in erythroid elements in the bone marrow.<sup>146</sup> There is no hemolysis; in fact, red cell survival is prolonged.<sup>181</sup> Treatment with a combination of thyroxine, cortisone, and growth hormone corrects both the anemia and the marrow hypoplasia<sup>153</sup> and such treatment is more effective than any single hormone given by itself. Combined adrenalectomy and thyroidectomy results in an anemia that is similar, but not identical, to that found after hypophysectomy.<sup>150,153</sup>

As is the case with the anemia of hypothyroidism (page 711), panhypopituitarism probably produces its effects on erythropoiesis chiefly by reducing tissue oxygen consumption.<sup>153</sup> The organism reacts to this

decreased need for oxygen by secreting less erythropoietin, and the red cell mass diminishes until a new equilibrium between oxygen supply and demand is established. This hypothesis is supported by the observations that (1) tissue oxygen consumption is low in the hypophysectomized rat, even if the red cell mass is restored to normal<sup>153</sup>; (2) once equilibrium has been established, the marrow of the hypophysectomized animal will respond to hypoxia, bleeding, or cobalt administration<sup>153,161</sup>; (3) correlation between oxygen consumption and rate of erythropoiesis can be demonstrated in hypophysectomized animals given thyroxine or 2,4 dinitrophenol<sup>153</sup>; and (4) erythrocyte 2,3 DPG levels, which increase when tissue oxygen delivery is compromised, are normal in patients with panhypopituitarism.<sup>182</sup>

develops because there is an additional pathogenetic factor, namely, failure of the marrow to increase red cell production sufficiently to compensate for the shortened survival of the red cells ("relative marrow failure") (Chapter 19). These illnesses have a *hemolytic component*, but it is misleading to include them with the hemolytic anemias.

More narrowly defined, the term *hemolytic anemia*, or better still *hemolytic disorders*, is limited to those conditions in which the rate of red cell destruction is accelerated and the ability of the bone marrow to respond to the stimulus of anemia is unimpaired. Such a definition is of practical as well as semantic importance. One may expect hemolytic disorders as here defined to be associated with features that serve to set them apart from other forms of anemia, namely, signs of accelerated erythrocyte destruction together with vigorous blood regeneration. In general, a similar picture is not observed in anemias with a mild hemolytic component and relative marrow failure. Once a clearly hemolytic process has been detected, the diagnostic possibilities are reduced, and an orderly plan of investigation leading to a specific diagnosis can be formulated.

The distinction between frankly hemolytic anemias and those associated with relative marrow failure can best be understood in quantitative terms (Table 20-1). Under

**Definitions**

Hemolytic anemias are anemias that result from an increased rate of red cell destruction. Strictly interpreted, however, such a definition would include a number of common but kinetically complex anemias, such as the anemia of chronic disorders and of renal disease, anemia associated with vitamin B<sub>12</sub> or folate deficiency, and even iron-deficiency anemia. In these, the rate of red cell destruction is modestly increased, but not to a degree that would, by itself, lead to anemia. The anemia

Table 20-1. Representative Values for Rates of Hemoglobin Production and Destruction in Several Types of Anemia

	Hemoglobin Concentration (g/dl)	Total Circulating Hemoglobin* (g)	Erythrocyte Survival (days)	Hemoglobin Produced and Destroyed† (g/day)
Normal subject	16.7	800	120	6.7
Relative marrow failure	10	480	60	8.0
Compensated hemolytic state	16.7	800	20	40
Hemolytic anemia	10	480	12	40

\*Based on an assumed blood volume of 4.8 l

†Calculated from the ratio  $\frac{\text{Total Circulating Hemoglobin (g)}}{\text{RBC Survival (days)}}$ 

maximal stimulation, the normal marrow is capable of undergoing hyperplasia until its production rate is increased about six- to eight-fold.<sup>7</sup> With optimal marrow compensation, it is theoretically possible for the survival of red cells in the circulation to decrease from the normal 120 days to as little as 15 to 20 days without anemia developing. Such an increase in both destruction and production of erythrocytes can produce a compensated hemolytic state without anemia being present, usually known as *compensated hemolytic disease*. On the other hand, when red cell survival becomes so short that anemia develops in spite of a vigorous erythropoietic response, the term *hemolytic anemia* is appropriate.

## Development of Knowledge Concerning the Hemolytic Anemias

Galen, in AD 150, described a patient who developed jaundice after being bitten by a viper.<sup>10</sup> He postulated that, in this and in certain other cases, jaundice was not the result of liver disease, but instead was of splenic origin. In the modern era, Vanlair and Masius were probably the first to report a patient with hemolytic anemia,<sup>23</sup> although the dark urine of paroxysmal nocturnal hemoglobin-

uria had been noted even earlier (page 934). Their patient had anemia, acholuric jaundice, splenomegaly, and abnormally small red cells (presumably spherocytes), and they termed the condition "microcythemia." They proposed that the jaundice arose from exaggerated destruction of erythrocytes and transformation of the liberated hematin to bilirubin.

In 1890 and 1893, Wilson and Stanley reported, in six members of a single kindred, the occurrence of a chronic condition characterized by splenomegaly, icterus, a predisposition to gallstones, and, in one of the members, progressive anemia resulting in death.<sup>23</sup> Almost certainly, the disease they described is the one we know today as hereditary spherocytosis (Chapter 21). Around the turn of the century, Minkowski<sup>19</sup> and Chauffard<sup>1</sup> published comprehensive descriptions of this congenital form of hemolytic anemia and Chauffard called attention to the increased osmotic fragility of the erythrocytes. The term "hemolytic" was probably coined by William Hunter, who used it to distinguish anemias caused by excessive blood destruction from "hemogenic" anemias, such as pernicious anemia.<sup>14</sup>

Hayem, in 1898,<sup>13</sup> and, later, Widal, Abrami, and Brulé<sup>24</sup> (1907-1909) pointed out that, whereas the classic congenital hemolytic anemia described by Minkowski

and Chauffard often caused few symptoms, another type, which they regarded as acquired, frequently was associated with severe anemia and profound illness. In the acquired type they included cases of excessive blood destruction associated with various infections or intoxications, as well as cases of unknown cause. In the latter, autohemagglutination was often noted. Chauffard and Troisier<sup>5</sup> were able to demonstrate autohemolysins in the serum of a few patients with acute, acquired hemolytic anemia, in contrast to their absence in the congenital cases, and spoke of "hemolytic icterus."

Despite these studies, doubt persisted for many years that there is a truly "acquired" form of hemolytic jaundice. Apparently acquired cases commonly were ascribed to aggravation of a latent, congenital illness. Some 20 years passed before Lederer<sup>17</sup> and Brill<sup>2</sup> called attention to an acute, idiopathic hemolytic anemia which was associated with infectious disease and from which rapid recovery ensued following blood transfusions. Subsequently, similar cases attracted attention,<sup>11</sup> and the fact that they differed from cases of congenital hemolytic jaundice in crisis ultimately came to be recognized. The existence of acquired hemolytic anemia in contrast to the congenital form was clearly established by Dameshek and Schwartz,<sup>8</sup> who demonstrated abnormal hemolysins in the blood of patients suffering from acute hemolytic anemia and showed that spherocytosis and increased osmotic fragility can develop during the course of such anemia in man as well as in acute hemolytic anemia produced experimentally in animals.

The subsequent development of the field can be credited in large part to the growth of understanding of the metabolism of the red corpuscle (Chapter 3), the structure and function of its membrane, and the abnormalities resulting from alterations in the hemoglobin molecule (Chapter 24). Important advances were also made by the application of serologic techniques to the study of hematologic disorders.

Between 1930 and 1950, several cases of congenital hemolytic anemia which differed

from classic hereditary spherocytosis in that there was no spherocytosis, erythrocyte osmotic fragility was normal, and splenectomy was not therapeutically beneficial, were reported.<sup>1,6,12,16,21</sup> Crosby<sup>6</sup> and Kaplan and Zuelzer<sup>16</sup> applied the term "congenital (or familial) non-spherocytic hemolytic anemia" to such cases. It soon became apparent that this designation did not refer to a single disease entity. The autohemolysis test of Selwyn and Dacie<sup>20</sup> (page 735) served not only to detect some of these illnesses, but also to separate them into two categories, type I and type II. Results of the test also suggested that in type II disease glycolysis might be defective. The discovery by Carson et al<sup>3</sup> of glucose-6-phosphate dehydrogenase deficiency, followed by the demonstration by Valentine and coworkers<sup>22</sup> that a specific glycolytic enzyme (pyruvate kinase) was deficient in the red cells of patients with type II congenital nonspherocytic hemolytic anemia, led to an intensive search for, and discovery of, many other red cell enzymatic defects associated with hemolytic disease (Chapters 22, 23).

## Pathogenesis and Classification

The disorders associated with hemolytic anemia have been classified in various ways, none of which is entirely satisfactory. On clinical grounds they have been divided into *acute and chronic forms*, but such a division is of limited usefulness since acute episodes may develop during the course of chronic disorders. Of somewhat greater utility is a classification based on the site of hemolysis, ie, whether it is predominantly within the circulation ("intravascular") or within tissue macrophages ("extravascular"). Since the intravascular hemolytic disorders are accompanied by unique manifestations, such as hemoglobinemia, hemoglobinuria, and hemosiderinuria, the classification is easily made and often serves to limit the diagnostic possibilities<sup>83</sup> (Table 20-2). On the other hand, since most hemolytic diseases are characterized by extravascular red cell destruction,

**Table 20-2. Hemolytic Anemias Characterized by Predominantly Intravascular Red Cell Destruction**

- 1 Paroxysmal nocturnal hemoglobinuria (Chapter 29)
- 2 Disorders associated with erythrocyte fragmentation (Chapter 28)
- 3 Certain immunohemolytic anemias (Chapter 27)
  - a Transfusion reactions resulting from ABO iso-antibodies
  - b Paroxysmal cold hemoglobinuria
  - c Some instances of idiopathic autoimmune hemolytic anemia
- 4 Those associated with certain infections
  - a Blackwater fever in *falciparum* malaria
  - b Clostridial sepsis
- 5 Those caused by certain chemical agents
  - a Intravenous administration of distilled water
  - b Snake and spider venoms
  - c Arsenic poisoning
  - d Acute drug reactions in association with glucose-6-phosphate dehydrogenase deficiency
- 6 Thermal injury

detection of this mode of hemolysis still leaves one with a large number of diagnostic possibilities.

Hemolytic disorders also may be divided into inherited and acquired varieties. This division forms the basis for a classification that, as a rule, is the most useful to the clinician (Table 20-3). The classification also has pathogenetic significance, for the fundamental nature of hereditary lesions is quite different from that of acquired ones. Excessive destruction of erythrocytes may occur either because of an *intrinsic* defect in the cell itself or because of the action of *extrinsic* agents on normally constructed cells. As a general rule, the intrinsic defects are *inherited* and the extrinsic ones are *acquired*. There are only a few known exceptions to this generalization; these include (1) paroxysmal nocturnal hemoglobinuria (Chapter 29), an acquired disorder characterized by an *intrinsic* red cell defect; (2) certain inherited intrinsic defects (eg, the most common form of glucose-6-phosphate dehydrogenase deficiency) that are associated with no ill effects in the absence of an extrinsic agent, usually a drug (Chapter 23); and (3) thermal injury, which

induces an acquired, *intrinsic* erythrocyte defect.

Intrinsic and extrinsic abnormalities have been distinguished from one another by performing cross-transfusion erythrocyte survival studies (Table 20-4). Thus, it was shown that when normal erythrocytes were transfused to patients in whom there was an extrinsic cause for hemolysis the donated cells were destroyed as rapidly as the patient's own. If, on the other hand, the patient's corpuscles were removed from their unfavorable environment and were transfused to a normal recipient their survival time was normal.<sup>17</sup> In contrast, when the disorder was due to an intrinsic defect of the red cells the patient's cells, when given to a normal recipient, were disposed of more rapidly than those of the recipient; the latter's erythrocytes, if transfused into the patient, maintained a normal "life span." Such cross-transfusion experiments are not required in the study of the great majority of hemolytic anemias today, but they served to clarify the pathogenesis of hemolytic anemias before more readily applicable investigation procedures had been devised.

The inherited, intrinsic disorders of the erythrocyte can be subdivided into five groups, depending upon which major erythrocyte structure or metabolic pathway is impaired. Thus, there are defects affecting the membrane, the glycolytic pathway, glutathione metabolism, and the hemoglobin molecule (Table 20-3). There is also a small, miscellaneous group of disorders resulting from deficiencies of enzymes not associated with glycolysis or glutathione metabolism.

The acquired hemolytic anemias may be subdivided into eight groups, depending upon the nature of the extrinsic hemolytic factor. These factors include antibodies, physical trauma, infectious agents, physical agents, chemical agents, hypophosphatemia,<sup>15</sup> and liver disease ("spur cell anemia," Chapter 19). A separate category must be provided for paroxysmal nocturnal hemoglobinuria, which is of unknown cause, but, as noted previously, is unique in that it is due to an intrinsic abnormality of the red cell.

Table 20-3. Etiologic and Pathogenetic Classification of the Hemolytic Disorders

- I Inherited hemolytic disorders**
- A Defects in the erythrocyte membrane (Chapter 21)**

**Table 20-4. The Cross-Transfusion Erythrocyte Survival Technique for Distinguishing Intrinsic and Extrinsic Erythrocyte Abnormalities**

Donor	Recipient	Erythrocyte Survival	
		<i>Intrinsic abnormality</i>	<i>Extrinsic abnormality</i>
Patient	Normal subject	Reduced	Normal
Normal subject	Patient	Normal	Reduced

Most of these different forms of hemolytic anemia will be discussed in the chapters that follow. In this chapter, those clinical and laboratory aspects that apply to all forms of hemolytic anemia will be considered along with an approach to the utilization of such information for detection of hemolytic anemia and for arriving at a specific etiologic diagnosis. Finally, the acquired hemolytic anemias resulting from infectious, chemical, and physical agents and hypophosphatemia will be discussed.

## Clinical Manifestations

Although there are a large number of hemolytic disorders (Table 20-3), the clinical features of hemolysis associated with them are much the same. In general, the manifestations of hemolytic anemia depend upon the duration of the process as well as its severity. Thus, chronic congenital hemolytic anemia can usually be distinguished from acute acquired hemolytic anemia on clinical grounds, as will be indicated below. When the onset of acquired hemolytic anemia is insidious, however, the distinction may be more difficult.

### Chronic Congenital Hemolytic Anemia

The major clinical features of congenital hemolytic anemia are related to anemia, jaundice, the occurrence of crises, splenomegaly, and the development of cholelithiasis. Less common manifestations include chronic leg ulcers and bony abnormalities.

### Manifestations of Anemia

The severity of the anemia varies greatly from one patient to another, even among those who have the same illness. Those with severe disease ordinarily are detected shortly after birth or within the first year of life. Severe pallor and the cardiovascular manifestations of anemia (Chapter 13) are the usual findings, and the latter may be serious enough to require treatment with blood transfusions.

More commonly, anemia is moderate to mild because the shortened erythrocyte survival is partially compensated for by increased activity of the bone marrow. Often the patients accommodate themselves remarkably well to the anemia, and there may be few symptoms. A moderately pallid complexion may be the only sign. Under such circumstances, detection frequently is delayed until later in childhood.

Finally, some patients have no anemia at all. The disease may then remain unsuspected until late in adult life, unless jaundice, a "crisis," or complications of gallbladder disease draw attention to the conditions. Sometimes such cases are only discovered in the course of a family study.

### Jaundice

In some instances, jaundice is first noted in the neonatal period.<sup>47,49</sup> Indeed, the anemia and jaundice may become so intense that immunohemolytic disease of the newborn (page 895) is simulated, kernicterus is feared, and an exchange transfusion is performed.<sup>47</sup> In many older children and adults with con-

genital hemolytic anemia, icterus is absent or mild enough to pass unnoticed. Careful inquiry may elicit a history of episodes of jaundice associated with trivial infections or unusual exertion. In others, jaundice is persistent, but never becomes intense (see page 726). Often slight scleral icterus is the only sign of hemolytic disease, and the description "more yellow than sick" has been appropriately applied to such patients.

The jaundice of hemolytic disease is *acholuric*; the bilirubin, being unconjugated, is not excreted into the urine (page 211). Furthermore, pruritus is absent. These features help to distinguish the icterus of hemolytic disease from that found with disorders of the hepatobiliary system.

### Crises

In the chronic congenital hemolytic diseases, long periods of relatively asymptomatic disease may be punctuated by episodes of acute anemia, icterus, or other manifestations of a so-called "crisis." Usually these episodes appear to be precipitated by an intercurrent infection, especially an upper respiratory infection<sup>34</sup>; "epidemics" have been reported in which several family members were affected simultaneously.<sup>37,45,46</sup> Most often, such crises result from transient failure of red cell production<sup>34,37,39,45</sup> ("aplastic" crisis), and the abrupt development of reticulocytopenia is a characteristic feature (Fig. 20-1). Mild leukopenia and thrombocytopenia may accompany the episode.<sup>37,45</sup> The bilirubin level does not increase and may even decrease somewhat. The aregenerative phase usually lasts 5 to 12 days.

Less commonly, crises may result from an increase in the rate of red cell destruction, possibly because of increased splenic activity ("hemolytic crisis").<sup>36,41</sup> In such episodes the degree of jaundice and the reticulocyte count increase and the spleen may enlarge. A third type of crisis comes about because of complicating folate deficiency ("megaloblastic crisis"), to which patients with chronic hemolysis appear to be particularly prone (Chapter 14, page 579). The onset of megaloblastic

crises tends to be more gradual than that of the other two and is unrelated to complicating infections.

If the clinician sees the patient for the first time because of a crisis, the sequence of events may well suggest an acute disease of recent onset rather than a chronic, congenital illness.

### Splenomegaly

The spleen commonly is enlarged in patients with congenital hemolytic anemias, except for those with sickle cell anemia (page 831). Most often the degree of enlargement is mild to moderate, but occasionally the spleen is huge. At times the splenomegaly leads to discovery of the disease because the spleen is detected on a routine physical examination. Alternatively, the spleen may attract attention because of a vague sensation of oppression or weight in the left side of the abdomen, or, less commonly, because it is the site of an attack of pain.

### Cholelithiasis

The development of gallstones and complications therefrom may play a prominent role in the clinical manifestations of congenital hemolytic anemias.<sup>31,42,50</sup> Symptoms of gallbladder disease may be the initial manifestations of a hemolytic process and may be the ones that bring the illness to the attention of a physician. The stones are of the pigment type and are presumed to be a consequence of the continuously excessive bilirubin load presented to the gallbladder. Cholelithiasis has been observed in young children,<sup>38</sup> but is rare prior to puberty.<sup>31</sup> The incidence increases with age; 85% of adults with hereditary spherocytosis are affected.

### Leg Ulcers

Chronic ulcerations of the legs are a peculiar and relatively uncommon complication of chronic hemolytic disease. They are particularly characteristic of hereditary spherocytosis<sup>32,43,51</sup> (Fig. 21-1, page 753) and sickle

Fig. 20-1 Severe aplastic crisis in a patient with hereditary spherocytosis who previously had well compensated hemolysis. Note the profound reticulocytopenia during the early phases of the reaction, followed by reticulocytosis. As occurred in this patient, jaundice often decreases during the crisis, and mild, transient leukopenia and thrombocytopenia are not unusual. (Plotted from the data of Owen<sup>45</sup>)

cell anemia<sup>35,53</sup> (Fig. 25-6, page 842), but may also be seen in association with other hemolytic disorders.<sup>30,41,50</sup> The ulcers often are bilateral and tend to involve the areas

over the medial or lateral malleoli or those above these prominences. When severe, they may extend a considerable distance up the leg and may completely surround it. They tend

to be chronic or recurrent, and, upon healing, leave indurated and pigmented areas of the skin.<sup>32</sup> Interruption of the hemolytic process, eg, by splenectomy in hereditary spherocytosis, is followed by healing of the ulcers.<sup>43,51</sup>

### ***Skeletal Abnormalities***

When hemolytic anemia is severe during active phases of growth and development, the pronounced expansion of the erythroid bone marrow may lead to a tower-shaped skull, thickening and striation of frontal and parietal bones, maxillary and dental abnormalities, and other distortions of bony structures.<sup>33</sup> Such abnormalities are particularly characteristic of severe thalassemia major and are described fully in the chapter dealing with that illness (page 863). They may also occur in patients with sickle cell anemia (page 832) and in exceptional patients with other forms of congenital hemolytic anemia.<sup>33,50</sup>

### ***Acquired Hemolytic Anemia***

If hemolytic anemia develops *acutely*, eg, after the transfusion of incompatible blood, or the ingestion of an "oxidant" drug by patients with glucose-6-phosphate dehydrogenase deficiency, the symptoms may suggest an acute febrile illness. Some instances of autoimmune hemolytic anemia, thrombotic thrombocytopenic purpura, and other hemolytic disorders may also begin abruptly.<sup>52</sup> Aching pains in the back, abdomen, or limbs are common, as are headaches, malaise, vomiting, shaking chills, and fever.<sup>52</sup> Abdominal pain may be severe, and the accompanying muscular spasm and rigidity may simulate the signs of an acute abdominal condition requiring surgical treatment.<sup>52</sup> Profound prostration and shock may develop, followed by oliguria or anuria (Chapter 11, page 480). Pallor, jaundice, tachycardia, and other symptoms of severe anemia may be prominent.

More often, acquired hemolytic anemia begins *insidiously*. The anemia develops gradually over a period of weeks or months. Cardiovascular adjustments to the anemia

may be quite good and there may be few symptoms. The clinical picture may be similar to that described for congenital hemolytic disease. Pallor, scleral icterus, or a jaundiced complexion may be the first evidence of illness, and often is noticed by friends or associates before it is appreciated by the patient or his family. When anemia is more severe, the patient commonly complains of weakness, fatigability, dyspnea, or other cardiovascular symptoms (page 535). As in congenital hemolytic anemia, the course may be interrupted by aplastic crises.<sup>48</sup>

In other instances, the clinical setting may be dominated by the manifestations of an underlying disease of which the hemolytic anemia is one manifestation. Thus, for example, signs and symptoms of lymphoma, lupus erythematosus, or mycoplasma pneumonia may overshadow those of the associated hemolytic process.

## **Laboratory Manifestations**

Laboratory findings in hemolytic anemia can be divided conveniently into three groups: (1) those related to the increase in erythrocyte destruction, (2) those related to the compensatory increase in the rate of erythropoiesis, and (3) those found only in particular varieties of hemolytic anemia and therefore useful in differential diagnosis.

### ***Signs of Excessive Red Cell Destruction (Table 20-5)***

#### ***Erythrocyte Survival***

The life span of the red cell can be measured by any of the methods described in Chapter 5 (page 195), but the method based on random labeling with <sup>51</sup>chromium has been used much more frequently than the others. As measured by this technique, the half-disappearance time ( $t_{1/2}$  Cr) is nearly always reduced in hemolytic disease, but the degree of reduction varies from one patient to another, even among those with the same disease (Fig. 20-2). On the average,  $t_{1/2}$  Cr is reduced to about half the normal value;

**Table 20-5. Laboratory Signs of Accelerated Red Cell Destruction**

- A Decreased erythrocyte life span
- B Increased catabolism of heme
  - 1 Increased serum unconjugated bilirubin
  - 2 Increased endogenous carbon monoxide production
  - 3 Increased rate of bilirubin production
  - 4 Increased rate of urobilinogen excretion
- C Increased serum lactate dehydrogenase activity
- D Signs of intravascular hemolysis
  - 1 Hemoglobinemia
  - 2 Absence of haptoglobin\*
  - 3 Hemoglobinuria
  - 4 Hemosiderinuria
  - 5 Methemalbuminemia
  - 6 Reduced serum hemopexin  $\curvearrowright$

\*Also occurs in association with predominantly extravascular hemolytic processes

however, because of the nonlinear relation between  $t_{1/2}$  Cr and erythrocyte life span, the reduction in the latter is greater than might be supposed. Thus, for example, a 50% reduction in  $t_{1/2}$  Cr corresponds to an erythrocyte life span of about 30 days, or 25% of normal. The  $t_{1/2}$  tends to be lowest in patients with the greatest degree of anemia, but the correlation is not a very close one.

Erythrocyte life span determinations are time-consuming and expensive. Furthermore, they are rarely necessary because the degree of red cell survival usually can be approximated by analysis of more easily obtained data, such as serial observations of the degree of anemia, reticulocytosis, and jaundice. For these reasons, determination of red cell survival should not be considered a routine procedure in examination of patients suspected of having hemolytic anemia. Instead, it should be reserved for those presenting especially difficult diagnostic problems.

### **Catabolism of Heme**

In hemolytic disease the heme moiety of hemoglobin is catabolized at a greatly accelerated rate, and excretion of the principal heme catabolites—bile pigments and carbon monoxide—is proportionately increased

(Chapter 5). These alterations provide clinically useful signs of hemolysis.

**SERUM BILIRUBIN.** The amount of bilirubin in the circulation depends partly on the rate at which the bilirubin is formed and partly on the efficiency with which it is excreted by the liver. It is not surprising, therefore, that the serum bilirubin level is an unreliable index of the rate of red cell destruction. Occasionally, it falls within the normal range despite brisk hemolytic disease. The total serum bilirubin was normal (less than 1.0 mg/dl) in 25% of 72 patients with hereditary spherocytosis and ranged from 1.0 to 4.8 mg/dl in the remaining 75% (Fig. 20-3).<sup>101</sup> Similarly, it was increased in 55% of 120 patients with immunohemolytic anemia and normal in the remaining 45%.<sup>100</sup> Except during the neonatal period, values greater than 5 mg/dl are unusual in patients with hemolytic anemia and suggest coexisting hepatic dysfunction.

The increased serum bilirubin in hemolysis almost always consists of the unconjugated ("indirect reacting") pigment. The conjugated fraction remains within normal limits, and no bilirubin is found in the urine. A number of other illnesses are associated with unconjugated bilirubinemia (Table 20-6), and these must be distinguished from hemolytic anemia.

**RATE OF HEME CATABOLISM.** Because the serum level of unconjugated bilirubin is a poor index of the rate of heme catabolism, and because it remains within normal limits in a sizable proportion of patients with hemolytic disease, there is need for more sensitive and quantitative techniques. As yet, no such method that is both simple and accurate has been developed. Determinations of the rate of endogenous carbon monoxide production or of bilirubin turnover (page 216) provide accurate assessments of the rate of heme catabolism. With these methods, values of about 2 to 10 times the normal rate have been detected in small groups of patients with hemolytic disease. However, at the present stage of development, these methods are too complex for the routine clinical laboratory.

Fig 20-2. Erythrocyte life span ( $t_{1/2}$ ) as measured by  $^{51}\text{Cr}$  tagging of red cells in several hemolytic states. Each dot represents the results in a single patient. The horizontal lines indicate the means and the shaded areas outline the normal range. The data are derived from the examination of 22 patients with hereditary spherocytosis,<sup>61,77,84,112,117</sup> 15 with pyruvate kinase deficiency,<sup>30, 55, 65, 74, 89, 92, 104, 104, 109, 120</sup> 16 with thalassemia major,<sup>83, 125</sup> 13 with sickle cell anemia,<sup>121</sup> 7 with S-C disease<sup>121</sup> and 22 with immuno-hemolytic anemia.<sup>75, 117</sup>

Quantitative measurements of fecal urobilinogen excretion (page 217) are more available. They provide a more sensitive index of hemolysis than does the serum bilirubin level; however, they have the undesirable feature of requiring the accurate collection and processing of timed fecal specimens. Miller et al found that if the excretion of urobilinogen was expressed in relation to the estimated circulating hemoglobin (Hb) mass (the "hemolytic index"), the normal value was 11 to 21 mg/day/100 g Hb.<sup>102</sup> In 12 patients with hemolytic disease, values ranged from 32 to 792 mg/day/100 g Hb and averaged 255 mg/day/100 g Hb. Since formation of

urobilinogen depends upon intestinal bacteria (page 213), falsely low values are to be expected in patients receiving broad-spectrum antibiotics.

### Lactate Dehydrogenase

Serum lactate dehydrogenase (LDH) activity often is increased in hemolytic anemia, although not to as great an extent as in megaloblastic anemia (see Fig. 14-6, page 573). In seven patients with various types of hemolytic anemia, serum LDH averaged 580 U/ml and ranged from 285 to 1160 U/ml<sup>82</sup> as compared with the upper limit of normal

Fig 20-3 Total serum bilirubin values in 48 normal subjects and 72 patients with hereditary spherocytosis (From the data of MacKinney et al.<sup>101</sup>)

of 240 U/ml. If LDH isozymes are determined, LDH-2 predominates in hemolytic anemia, whereas LDH-1 predominates in megaloblastic conditions.<sup>127</sup> The increase in LDH is thought to result from liberation of the erythrocyte enzyme into the plasma during hemolysis.<sup>82</sup>

#### *Signs of Intravascular Hemolysis*

When erythrocytes are destroyed within the circulation, and also when extravascular destruction is so rapid that the capacity of the reticuloendothelial system is exceeded, hemoglobin is released into the plasma. The

hemoglobin and its heme group are disposed of by several mechanisms (page 205), and characteristic laboratory abnormalities are found (Table 20-5, D).

**HEMOGLOBINEMIA.** At low concentrations, plasma hemoglobin may be measured by means of the benzidine reaction,<sup>90,124</sup> which detects not only hemoglobin but also any other heme pigments that may be present. If special precautions are observed to avoid artifactual hemolysis during collection of blood, normally values of less than 0.001 g/dl of plasma are found. Plasma usually appears visibly red when hemoglobin exceeds

\*Modified from LW Powell.<sup>110</sup>

0.05 g/dl. At levels greater than 0.1 g/dl, hemoglobin can be measured directly by the cyanomethemoglobin method (page 114).

Plasma hemoglobin levels were found to be normal in patients with most hereditary hemolytic anemias, including hereditary spherocytosis, but values of 0.015 to 0.06 g/dl were noted in patients with sickle cell anemia and thalassemia major.<sup>76</sup> Levels also were increased in severe, acquired, immunohemolytic anemia, at times reaching 0.1 g/dl.<sup>76</sup> Particularly high values, up to 1.0 g/dl, are found only in patients with disorders associated with predominantly intravascular hemolysis.<sup>88</sup>

**ABSENCE OF HAPTOGLOBIN.** When hemoglobin (Hb) first appears in plasma, it becomes bound to haptoglobin (Hp) and the

HpHb complex is removed by the hepatocyte (page 207). Since there is no compensatory increase in Hp synthesis, Hp tends to disappear from the plasma in hemolytic diseases. Plasma haptoglobins may be measured by methods based on the peroxidase activity of the HpHb complex<sup>106</sup> or by electrophoretic<sup>123</sup> or chromatographic<sup>100</sup> measurement of hemoglobin binding capacity.

Absence of haptoglobin is one of the most sensitive signs of hemolysis; it is so sensitive, in fact, that it occurs even in hemolytic diseases that are not associated with hemoglobinemia, such as hereditary spherocytosis,<sup>70</sup> hereditary elliptocytosis,<sup>70</sup> and pyruvate kinase deficiency.<sup>50</sup> In most patients, haptoglobin was found to be absent whenever red cell destruction exceeded twice the normal rate, regardless of diagnosis.<sup>70</sup> However, haptoglobin levels increase in response to infections, malignant disease, or steroid therapy, and when any of these conditions complicated the hemolytic state, haptoglobin was demonstrable.

**HEMOGLOBINURIA.** If plasma hemoglobin exceeds the haptoglobin binding capacity, hemoglobin dimers are excreted into the urine, resulting in hemoglobinuria. Urine that contains hemoglobin ranges in color from faint pink to deeper red, or even to an almost black color similar to that of a "cola" beverage. The color depends on the concentration of hemoglobin as well as on the oxidation state and degree of dissociation of the heme group.

Hemoglobinuria can be distinguished from hematuria (whole red blood cells in the urine) by microscopic examination of a freshly voided urine specimen. Urine also may be red because of certain drugs (pyridium, antipyrine) or food (beets) taken by the patient, or because of porphyrinuria (Chapter 32) or myoglobinuria. Of these various red urinary pigments, only hemoglobin and myoglobin produce a positive reaction in the commonly available tests for occult blood, which are based on the benzidine or orthotoluidine<sup>69</sup> reactions (Occultest or Hemastix, Ames Laboratories, Elkhart, Indiana.)

Hemoglobinuria must be distinguished from *myoglobinuria*, which occurs as the result of massive muscle injury by trauma,<sup>71</sup> electric shock, arterial thrombosis,<sup>72</sup> certain toxins ("haft" disease),<sup>63 90, 122</sup> Malayan sea-snake-bite,<sup>113</sup> "idiopathic" myoglobinuria,<sup>116</sup> myophosphorylase deficiency (McArdle's disease),<sup>62 118</sup> and other causes.<sup>116</sup> Myoglobin is a heme pigment of small molecular weight (17,000); it is not bound by haptoglobin and therefore does not accumulate to an appreciable extent in plasma. Thus, inspection of the plasma can help to distinguish myoglobinuria from hemoglobinuria, the presence of a red color favoring the latter. More precise identification is accomplished by electrophoresis on paper, on starch or acrylamide gels or by spectrophotometry. The last is facilitated by treatment with carbon monoxide since there is greater divergence between the bands of carboxyhemoglobin and carboxymyoglobin than between the oxygenated forms. Unlike hemoglobin, myoglobin remains in solution after 80% saturation of the urine with ammonium sulfate.<sup>67</sup>

### Urine Iron Excretion

Hemoglobin in the glomerular filtrate is partially reabsorbed by the proximal tubular cells, and the hemoglobin iron is incorporated into ferritin and hemosiderin. Subsequently, the iron-containing tubular cells are sloughed into the urine. Hemosiderinuria and increased urinary iron excretion, therefore, constitute reliable evidence that hemoglobinemia has occurred in the recent past.<sup>76 88</sup> However, following an acute episode of intravascular hemolysis, it may be several days before increased iron excretion can be detected, and the abnormality may persist for some time after the episode has terminated. In most conditions associated with chronic intravascular hemolysis, increased iron excretion is a constant finding whereas hemoglobinuria occurs only intermittently. The only non-hemolytic disorder in which increased iron excretion is found is hemochromatosis.<sup>87</sup>

*Hemosiderinuria* may be detected by means of a qualitative test based on the Prussian

blue reaction.<sup>70</sup> Alternatively, urinary iron may be determined spectrophotometrically after wet digestion of a measured urine specimen.<sup>114, 119</sup> The normal value for urinary iron excretion is less than 0.1 mg/day. In a variety of disorders associated with intravascular hemolysis, urinary iron was increased to between 3 and 11 mg/day.<sup>119</sup> Normal or nearly normal values were found in pernicious anemia and in hereditary spherocytosis. In nine patients with hemolysis from prosthetic cardiac valves, urinary iron was increased to 0.8 and even 10.8 mg/day.<sup>114</sup> After correction of the abnormality by insertion of a heterograft, urinary iron decreased exponentially with time, but did not reach normal levels until after 6 to 10 months.

It appears, therefore, that urinary iron determination may be a useful and consistent sign of intravascular hemolysis. However, it may not accurately reflect the current clinical situation because of its persistence after the process has terminated.

### Methemalbumin and Hemopexin

Hemoglobin in plasma is readily oxidized to methemoglobin, from which the heme group detaches relatively easily. The liberated heme becomes bound to hemopexin and also to albumin, forming methemalbumin (page 208). Hemopexin-heme and methemalbumin impart a coffee-brown color to plasma. With either, a spectral absorption band is observed at 620 to 630 nm, which, unlike a similar band in methemoglobin, will not disappear if hydrogen peroxide is added. Upon the addition of ammonium sulfide, the 620 to 630 nm band disappears and a band at 558 nm is formed (Schumm's test).<sup>115</sup>

The presence of these pigments suggests intravascular hemolysis.<sup>85</sup> They have also been observed in association with hemorrhagic pancreatitis.<sup>97</sup> Like haptoglobin, hemopexin can be depleted in the course of serving its function,<sup>103</sup> but this occurs much less regularly than with haptoglobin. Subnormal serum hemopexin values have been noted particularly in patients with thalassemia major or sickle cell anemia.<sup>103</sup>

### Signs of Accelerated Erythropoiesis

The laboratory measures relating to increased erythropoiesis are listed in Table 20-7. In general, these findings are detected in chronic hemolytic disease, and will appear at different time intervals following an acute hemolytic episode. They also occur following hemorrhage and after specific therapy for anemia due to iron, folate or vitamin B<sub>12</sub> deficiency. It is sometimes useful to divide the signs of accelerated erythropoiesis into those that reflect *total* erythropoiesis (eg, the degree of erythroid hyperplasia and the plasma iron transport rate) and those that reflect *effective* erythropoiesis (eg, the reticulocyte count and the erythrocyte iron turnover rate). In conditions associated with ineffective erythropoiesis (page 550), measures of total erythropoiesis are increased, but measures of effective erythropoiesis are not.

#### Reticulocytosis

An increase in circulating reticulocytes is among the simplest and most reliable signs of accelerated erythrocyte production. Reticulocytes are young red cells containing ribosomes (page 83). Methods for detecting and enumerating them have been discussed in Chapter 3 (page 119). For clinical purposes, reticulocytes most often are reported as a percentage of the number of erythrocytes in the sample evaluated. Expressed in this way, the normal range is 0.8 to 2.5% in men and 0.8 to 4.1% in women.<sup>60</sup> Theoretically,

this percentage can increase either because there are more reticulocytes in the circulation or because there are fewer mature cells. For this reason, some prefer to "correct" for anemia by multiplying the percentage by a ratio of the patient's VPRC (or hemoglobin) to an average normal value. Thus, the "corrected" reticulocyte count equals:

$$\text{Reticulocytes (\%)} \times \frac{\text{Patient's VPRC (1/l)}}{0.45}$$

Alternatively, it is possible to express reticulocyte counts in absolute numbers (reticulocytes per liter) by multiplying the red cell count by the reticulocyte percentage. In these terms, the average normal value is about  $90 \times 10^9/l$ .

However, even these corrected counts are not perfect indices of production, for the percentage of reticulocytes can also be altered by premature release from the marrow ("shift"). A *reticulocyte production index* (RPI) has been proposed to correct both for "shift" and for anemia.<sup>93</sup> It is calculated according to the formula:

$$\text{RPI} = \frac{\text{Reticulocyte percentage}}{\text{Reticulocyte maturation time (days)}} \times \frac{\text{Patient's VPRC (1/l)}}{0.45}$$

The degree of "shift" is related to the intensity of stimulation by erythropoietin. Thus, the maturation time of the reticulocyte (in the circulation) is taken to be 1.0 day at a VPRC of 0.45 l/l, 1.5 days at 0.35, 2.0 days at 0.25, and 2.5 days at 0.15.

Example: VPRC = 0.25 l/l, reticulocytes = 20%

$$\text{RPI} = \frac{20}{2.0} \times \frac{0.25}{0.45} = 5.5,$$

indicating that erythrocyte production is increased to 5.5 times the normal rate. Although this mode of expression probably is a more accurate reflection of the erythrocyte production rate, it has not been demonstrated that diagnostic precision is improved thereby.

In most varieties of hemolytic anemia, the reticulocyte count is consistently increased to levels that correlate fairly well with the severity of the process (Table 20-8). Exceptions

Immunohemolytic anemia <sup>77</sup>	12	28.4 ± 12.0	111 ± 11

\*Values are means ± 1SD  
 †Highest values occur following splenectomy

occur chiefly during aplastic crises. Thus, of 76 patients with hereditary spherocytosis, the reticulocyte count was normal in only one and less than 5% in only 8.<sup>101</sup> In contrast, in idiopathic immunohemolytic anemia a larger proportion of patients were found to have normal reticulocyte counts.<sup>109</sup> Values of less than 2% were found in 26% of 35 such patients. In these subjects, the picture appeared to be complicated by generalized hypoplasia or erythroid hypoplasia of the marrow, suggesting that the autoantibodies were directed against marrow elements as well as circulating erythrocytes.

When reticulocytes are increased, *polychromatophilia* and *fine stippling* (page 83) may be found on routinely stained smears of blood. Since reticulocytes, especially those that are prematurely released from a stimulated marrow, tend to be larger than normal cells, *macrocytosis* usually accompanies reticulocytosis (Table 20-8). Exceptions occur in hereditary spherocytosis and sickle cell anemia, diseases in which the intrinsic defect of the cell tends to decrease its size.

*Other Morphologic Findings in the Blood*

When hemolysis is brisk, nucleated erythrocytes may be found in the blood (*erythroblastosis*). Usually, these amount to less than 1% of all the nucleated cells in the blood. In infants, however, erythroblastosis may be much more striking, especially in hemolytic disease of the newborn (page 899).

*Neutrophilic leukocytosis and thrombocytosis* may accompany hemolytic anemia. These findings tend to be most common and most pronounced in acute hemolytic anemias. Leukocyte counts as high as  $132 \times 10^9/l$  have been recorded under such circumstances. Platelets are not only numerous, but also large in size. The changes are less pronounced in chronic hemolytic processes. However, leukopenia and thrombocytopenia are unusual findings in hemolytic disease. Their presence suggests such diagnoses as paroxysmal nocturnal hemoglobinuria, hemolysis accompanying systemic lupus erythematosus, or, in a minority of cases, idiopathic autoimmune hemolytic anemia.

*Bone Marrow*

The major alteration in the bone marrow in hemolytic anemia is *erythroid hyperplasia*. Although methods have been developed for quantitating the marrow erythroid mass<sup>91</sup> (page 61), these are not practical for routine clinical use. Consequently, erythroid hyperplasia must be detected by examination of marrow aspirates or biopsy specimens. Marrow examination should be considered a qualitative or semiquantitative technique, and is not suitable for precise calculation of production rates. It is important to remember that marrow specimens represent only a tiny sample of the marrow and may not always accurately reflect the degree of change.

In smears of aspirated specimens, erythroid

hyperplasia is manifested by a reduction in the M:E ratio (page 71). In hemolytic disease, the ratio usually is less than 1.5 and may be as low as 0.5. However, since the M:E ratio also may be decreased as the result of reduction in granulocyte precursors, the meaning of the ratio must be evaluated in relation to the total clinical picture. It is hazardous to judge the cellularity of the marrow from the cellularity of an aspirated specimen. Marrow *biopsy specimens* should be used for this purpose, and with them more accurate qualitative judgments regarding the presence of erythroid hyperplasia can be made.

#### *Ferrokinetic Studies (Chapter 4)*

The plasma iron transport rate (PITR) is considered to be a measure of total erythropoiesis and correlates well with the degree of erythroid hyperplasia.<sup>86,91</sup> The erythrocyte iron turnover rate (EITR) is a measure of effective erythropoiesis and correlates well with the reticulocyte production index (page 165). In hemolytic anemia, the PITR averages two to five times the normal rate, and the EITR is increased two- to four-fold<sup>86</sup> (Table 20-9). These ferrokinetic measures provide accurate information regarding rates of erythropoiesis. Nevertheless, they are

unnecessary in the overwhelming majority of patients because the reticulocyte count and other easily obtained determinations are simpler, faster, considerably less expensive, and nearly as accurate.

#### *Laboratory Findings Useful in Differential Diagnosis*

##### *Specific Morphologic Abnormalities*

A competent, careful examination of a well-prepared blood smear is the single most valuable procedure in defining the underlying disorder leading to hemolytic anemia. Detection of certain distortions of red cell shape is of particular diagnostic utility because their presence suggests only one or a few entities. Descriptive features of such poikilocytes have been presented in Chapter 13 (page 540). Their major characteristics are summarized in Table 13-3, and they are illustrated in Figure 13-2.

Spherical erythrocytes, or *spherocytes*, are the hallmark of hereditary spherocytosis (Chapter 21). They are also found in most patients with acquired immunohemolytic anemia (Chapter 27), thermal injury, hypophosphatemia, or certain kinds of chemical poisoning. Spiculated cells, or *acanthocytes*, indicate disturbed erythrocyte lipid com-

**Table 20-9. Ferrokinetic Measurements in Various Hemolytic Anemias (Mean Values)\***

\*Data from CA Finch et al.<sup>84</sup>

position; they occur in association with abetalipoproteinemia (Chapter 21) and the "spur-cell anemia" that occasionally accompanies hepatic cirrhosis (page 708). *Stomatocytes*, which suggest a disturbance in red cell cation content, are found in association with a rare inherited hemolytic disease (Chapter 21) and also occur as a transient abnormality in acute alcoholics. *Target cells* are characteristic of thalassemia (Chapter 26), the homozygous abnormal hemoglobin states (Chapter 25), and lecithin-cholesterol acyl transferase (LCAT) deficiency (Chapter 21); they also occur in nonhemolytic states, such as obstructive jaundice and following splenectomy. Oval cells or *elliptocytes* are the sine qua non of hereditary elliptocytosis (Chapter 21). *Sickle cell anemia* was named after the unmistakable sickle-shaped poikilocytes that characterize that illness (Chapter 25). Finally, large numbers of *schistocytes*, *helmet cells*, or other fragmented red cells suggest hemolysis associated with physical trauma to the erythrocyte or with diseases affecting small blood vessels (Chapter 28).

*Erythrophagocytosis* (page 202), or the presence in blood of phagocytic cells containing recognizable whole red cells, is an

uncommon finding. When detected, it suggests damage to the red cell surface, especially that induced by complement-fixing antibodies, but also by protozoan and bacterial infectious agents and certain chemical poisons.

*Autoagglutination* may be apparent in blood smears or even visible to the naked eye when the blood is allowed to flow along the side of a glass container. The phenomenon is particularly characteristic of immunohemolytic disease due to cold agglutinins (page 921). Autoagglutination must be distinguished from rouleau formation (page 1611), a manifestation of myeloma and related diseases and the phenomenon responsible for accelerated rates of erythrocyte sedimentation (page 126).

### The Osmotic (Hypotonic Saline) Fragility Test

The osmotic fragility test is a measure of the resistance of erythrocytes to hemolysis by osmotic stress. The test consists of exposing red cells to decreasing strengths of hypotonic saline solutions and measuring the degree of hemolysis. Many techniques have been described,<sup>81,107</sup> including a semiautomated method.<sup>79</sup> To construct the conventional osmotic fragility curve, percent hemolysis is plotted on the vertical axis against decreasing saline concentration on the horizontal axis. A symmetrical curve, sigmoidal in shape, is obtained in most subjects (Fig. 20-4). Alternatively, the data can be plotted on probability paper<sup>107</sup> or in the form of incremental hemolysis curves.<sup>81</sup>

Osmotic fragility can also be described in terms of the saline concentration at which hemolysis begins (normally, 0.45 to 0.50 g/dl) or at which it is complete (normally 0.30 to 0.33 g/dl). Especially useful is the median corpuscular fragility (MCF), the saline concentration at which 50% of the cells hemolyze (normally 0.40 to 0.455 g/dl). (See Appendix A for additional normal values.) Increased fragility is indicated by a shift of the curve to the left (Fig. 20-4, B) or a high value for MCF. Osmotic resistance (reduced

Fig 20-4 Normal and abnormal osmotic fragility curves. A, Normal curve. A', the moderate increase in osmotic fragility on incubation. B, Hereditary spherocytosis. B', greatly increased osmotic fragility following incubation. C, Acquired hemolytic anemia. D, Increased resistance of red corpuscles from a patient with thalassemia minor.

fragility) is signified by a rightward shift (Fig. 20-4,D) and a reduced MCF value.

Increased osmotic fragility is observed in conditions associated with spherocytosis (page 733). This may be because very little fluid needs to be absorbed by cells of spherical shape to bring them to the point at which their membrane is stretched to the bursting point (Fig. 21-4), but other factors such as "leakiness" of the membrane (increased permeability to cations) and the intracellular osmotic pressure may also be important (page 757). With prior incubation of sterile blood for 24 hours,<sup>20</sup> the increased osmotic fragility of spherocytes is greatly accentuated (Fig. 20-4, B-B'), whereas normal cells become only slightly more fragile (Fig. 20-4, A-A'). The osmotic fragility of unincubated blood may, in fact, be normal in some patients with hereditary spherocytosis, and incubation of the red corpuscles may be necessary to distinguish them from normal.

Increased resistance to breakdown in hypotonic saline solutions is observed in thalassemia, sickle cell anemia, and other disorders in which many leptocytes, including "target" cells, are found (Fig. 20-4, D). Sometimes a small proportion of unusually fragile cells may also be detectable in these conditions. With prior incubation, target cells and leptocytes may become even more resistant to osmotic stress and there is a further rightward shift of the curve.

Determination of osmotic fragility thus appears to be chiefly of value in confirming important morphologic findings, especially the presence of spherocytes but also that of leptocytes. It is unusual to find that the osmotic fragility test provides information that was not already available from an expert examination of a well-prepared, stained blood smear.

### **Mechanical Fragility**

The sensitivity of erythrocytes to physical trauma has been measured by shaking the cells in a flask with glass beads<sup>120</sup> or by traumatizing them in other ways.<sup>60</sup> The method must be carefully standardized if reproduc-

ble results are to be obtained. In general, mechanical fragility is increased in the presence of spherocytes, sickled cells, or agglutinated cells, but not with other types of poikilocytes.<sup>120</sup> The test has not been widely applied, since it provides little or no information that cannot be obtained by morphologic means or with the osmotic fragility test.

### **Autohemolysis**

The test for autohemolysis<sup>20,98,111</sup> depends on the incubation of sterile, defibrinated blood at 37° C for 48 hours and measurement of the amount of spontaneous hemolysis that occurs. Comparison is made with the amount of hemolysis occurring when glucose or ATP has been added prior to incubation. With normal blood, little hemolysis takes place in 48 hours and even less when glucose or ATP is added (Table 20-10). On the basis of the degree of autohemolysis and the correction by ATP and glucose, Selwyn and Dacie<sup>20</sup> defined two abnormal patterns, Type I and Type II (Table 20-10). With the Type I pattern, autohemolysis is only slightly to moderately increased and there is incomplete correction with either ATP or glucose. With the Type II pattern, autohemolysis is greatly increased and glucose has no effect, but ATP restores the value to normal. A third pattern was found in hereditary spherocytosis, namely, greatly increased autohemolysis with complete or nearly complete correction with either ATP or glucose.

Subsequent studies indicated that Type II autohemolysis is characteristic of pyruvate kinase (PK) deficiency<sup>50</sup> and that the Type I pattern occurs in glucose-6-phosphate dehydrogenase deficiency. However, the patterns are neither very sensitive nor completely specific. Thus, normal autohemolysis was found in some patients with mild PK deficiency and a Type I pattern in others.<sup>50</sup> Patterns characteristic of various enzyme deficiencies<sup>78,84 98,111</sup> are given in the footnote to Table 20-10.

The autohemolysis test now largely is of historic interest. The tediousness of the method, its lack of specificity and sensitivity,

Condition†	Autohemolysis (%/48 hr)†		
	No Additive	With Glucose	With ATP
Normal	2.0 (0.2-4.0)	0.3 (0.1-0.6)	0.2 (0.1-0.8)
Type I	3.0 (1-6)	1.3 (0.5-4.0)	1.0 (0.4-2.0)
Type II	13 (8-44)	15 (4-48)	1.0 (0.2-2.0)
Hereditary spherocytosis	16 (6-30)	3 (0.2-14)	3 (1-6)

†Values are means with approximate range in parentheses.

†Type I autohemolysis is typical of hereditary elliptocytosis, unstable hemoglobin disease, and deficiencies of glucose 6-phosphate dehydrogenase, glucose-phosphate isomerase, phosphoglycerate kinase, 2,3-diphosphoglycerate mutase, and 6-phosphogluconate dehydrogenase. Type II autohemolysis is found particularly in pyruvate kinase deficiency but also has been reported in deficiencies of hexokinase, ribose pyrophosphokinase, and 2,3-diphosphoglycerate mutase. A pattern similar to that of hereditary spherocytosis was found in triose phosphate isomerase deficiency.

and the availability of simplified spot tests for specific enzyme deficiencies<sup>85</sup> have greatly limited its value. It still has some utility as a screening test when enzymatic assays are not available.

#### Tests for Hemolytic Disorders Associated with Heinz-Body Formation

In certain disorders the hemolytic process depends on precipitation of hemoglobin, with the formation of inclusions known as Heinz bodies. These inclusions are rapidly removed by the spleen. Heinz-body formation is the principal mechanism of hemolysis in glucose-6-phosphate dehydrogenase (G6PD) deficiency and related disorders (Chapter 23), in unstable hemoglobin disease (Chapter 24), in the thalassemias (Chapter 26), and in certain kinds of chemical injury (page 743). Heinz bodies usually are not observed when ordinary staining procedures are employed, but require special supravital stains (page 29). Cells containing these inclusions may

be found in the blood during an acute drug reaction in subjects with G6PD deficiency and also in splenectomized individuals with unstable hemoglobin disease. However, when the spleen is intact, the inclusions are removed with such efficiency that cells containing them are rarely seen.

It is possible to induce Heinz-body formation in vitro by incubating erythrocytes with acetylphenylhydrazine.<sup>66</sup> The number, size, and rate of formation of the inclusions tend to be greater in cells from patients with the disorders listed above than in other individuals. However, the frequent occurrence of falsely positive results in many anemias has limited the usefulness of this procedure.<sup>84</sup>

The glutathione stability test<sup>64</sup> depends on the observation that, when sensitive cells are exposed to acetylphenylhydrazine, the glutathione level falls rapidly to low levels, whereas the rate and amount of fall are much less in normal cells. The test is technically difficult and infrequently used.

The ascorbate-cyanide test is a sensitive measure of abnormal susceptibility of hemoglobin to peroxidative denaturation.<sup>95</sup> It depends upon the coupled oxidation of ascorbate with oxyhemoglobin to produce hydrogen peroxide. When catalase is inhibited with cyanide, the glutathione-dependent system is required to protect peroxidative damage to hemoglobin. Two ml of whole blood are well-oxygenated to a bright-red color by swirling in air or oxygen. The blood is added to tubes containing 10 mg ascorbate, 5 mg glucose, and 2 drops 0.1 M cyanide, and the mixture is incubated at 37° C with agitation. Normal blood remains red, but in abnormal blood a dark-brown color is observed within two hours.

The test is quickly and easily performed and its reaction is strongly positive in deficiencies of G6PD or glutathione peroxidase and in some unstable hemoglobin disorders.<sup>84</sup> Lesser degrees of darkening were reported in deficiencies of glutathione reductase or pyruvate kinase and in individuals heterozygous for G6PD deficiency.

None of these screening procedures is entirely satisfactory, but the ascorbate-cyanide

test is preferable for routine use because it is so simple. More specific tests, such as enzyme spot tests<sup>65</sup> or the heat stability test for unstable hemoglobins (page 808), also are useful in the differential diagnosis of these disorders.

### Other Tests

Other important laboratory procedures for detecting and differentiating the hemolytic anemias are discussed in chapters dealing with specific entities. Thus, methods for identifying enzyme deficiencies<sup>65</sup> are discussed in Chapters 22 and 23. Those for detecting and defining abnormal hemoglobins appear in Chapter 24; the Coombs' test and other serologic techniques for evaluating immunohemolytic anemias are described in Chapter 27; and tests for paroxysmal nocturnal hemoglobinuria appear in Chapter 29.

## Diagnostic Approach

A final diagnosis of one of the hemolytic anemias is established by a process consisting of two distinct steps: first, demonstrating that a hemolytic anemia is present and, second, determining the specific cause of the condition. A common error made in clinical practice is the pursuit of the second objective before the first has been accomplished. This can be unproductive and wasteful in respect to time and money.

### *Establishing That Hemolytic Anemia Is Present*

The diagnosis of hemolytic anemia is essentially based on kinetic considerations. It requires a careful analysis of data that pertain to rates of red cell production (Table 20-7) and destruction (Table 20-5). In general, no single finding establishes the diagnosis; rather, it depends on a characteristic combination of findings, interpreted in the light of information from a carefully taken history. The presence of hemolytic anemia may be considered established by any of the following:

1. *Evidence of excessive red blood cell destruction and excessive red cell production occurring at the same time.* Perhaps the most common example of this type of evidence is the association of anemia, reticulocytosis, and unconjugated (indirect) hyperbilirubinemia together with historical information excluding other possible causes of these findings. Occult hemorrhage into an organ or a tissue space may simulate this picture, but only transiently (page 698).
2. *Evidence of persistent anemia despite increased erythropoiesis, in the absence of blood loss.* In situations of this type, anemia and reticulocytosis are observed, but jaundice is lacking. Since hemorrhagic anemia and the early stages of response to specific therapy of nutritional anemia may also produce this set of findings, efforts to exclude them from consideration are appropriate. In addition, a quantitative measure of heme catabolism, such as fecal urobilinogen excretion, may be useful in this setting. Still another practical approach to this problem is to make serial observations; if the anemia and reticulocytosis persist without evidence of continuing blood loss, hemolytic anemia is the only tenable diagnosis.
3. *Development of anemia at a rate exceeding that which can be accounted for by a total arrest of erythropoiesis.* A fall in blood hemoglobin concentration at a rate of 1.0 g/dl per week or faster implies hemolysis, blood loss, or rapid hemodilution. If the possibility of the last two can be excluded, the presence of hemolytic anemia is confirmed. This type of presentation might occur during an aplastic crisis in a patient with previously well-compensated disease (Fig. 20-1) or in one having an acute hemolytic reaction. The characteristic reticulocyte response may be suppressed or delayed under such circumstances, and jaundice may or may not be present.
4. *The occurrence of hemoglobinuria or other signs of intravascular blood destruction.* Such episodes may or may not be associated with other signs of hemolysis, de-

**Table 20-11. Conditions Sometimes Mistaken for Hemolytic Anemia**

D	Marrow invasion (myelofibrosis metastatic disease)
E	Myoglobinuria

pending on the amount of blood destroyed and the duration of the process. It is important to be certain that the urine pigment is, in fact, hemoglobin and not some other pigment (page 729).

#### *Conditions Sometimes Mistaken for Hemolytic Anemia (Table 20-11)*

As previously mentioned, the anemias due to acute hemorrhage and those due to partially treated deficiency states are characterized by transient anemia and reticulocytosis. They can usually be distinguished from hemolytic disease by the absence of icterus and by a rising VPRC on subsequent determinations.

Anemias caused by ineffective erythropoiesis often are accompanied by acholuric jaundice and by erythroid hyperplasia of the marrow; however, in these the reticulocyte count usually is not increased. In equivocal situations it may be necessary to measure erythrocyte survival, which will be distinctly shortened in hemolytic disease and normal or nearly so in association with ineffective erythropoiesis. The two conditions can also be distinguished by means of ferrokinetic studies (page 167).

A particularly confusing situation may arise following occult hemorrhage into the retroperitoneal space or other tissue compartments. When such hemorrhage occurs, anemia develops rapidly and reticulocytosis follows. Furthermore, indirect hyperbilirubinemia may occur as the result of reabsorption of the products of hemoglobin breakdown at

the site of hemorrhage. Thus, the picture of hemolytic anemia may be simulated in several ways. Diagnosis depends on detecting signs of the hemorrhage itself or of the disease process leading to it. If occult hemorrhage is suspected, serial observations usually clarify the situation, for, once the hemorrhage has ceased, the VPRC, reticulocyte count, and bilirubin values will return to normal.

In individuals with acholuric jaundice but without anemia, the differential diagnosis lies between a compensated hemolytic state and Gilbert's syndrome or other disorders of bilirubin catabolism (Table 20-6). It is usual to detect reticulocytosis or morphologic abnormalities of erythrocytes in the former. However, in mild compensated hemolytic disease, one cannot always be certain that the blood will be abnormal. Fasting induces an exaggerated increase in bilirubin levels in Gilbert's syndrome,<sup>110</sup> but the usefulness of this procedure in distinguishing Gilbert's syndrome from hemolytic anemia remains to be established. If the distinction is considered important, erythrocyte survival may be measured. However, if the disease is asymptomatic there may be little to gain from precise diagnosis.

Anemia associated with "marrow invasion" (Chapter 57) may be accompanied by erythroblastosis and bizarre abnormalities of erythrocyte shape. Mild reticulocytosis may develop because of premature release ("shift," page 731). There usually is no jaundice, however, and evidence of the invasive disease may be detected by examination of the bone marrow.

The differentiation of myoglobinuria from hemoglobinuria was discussed on page 729.

#### *Determining the Specific Cause*

The diagnostic analysis should begin with information from the medical interview and the results of the blood smear examination and a Coombs' test. From these data, five groups of patients can be distinguished.

1. *Those in whom the diagnosis is clear because of obvious exposure to infectious, chemical, or physical agents (page 740).*

2. *Those with Coombs-positive hemolytic anemia.* Such individuals may be presumed to have immunohemolytic anemia (Chapter 27). The subsequent investigation requires a search for an underlying disease as well as a serologic study of the nature of the antibody.
3. *Those with Coombs-negative, spherocytic hemolytic anemia.* Such patients probably have hereditary spherocytosis (Chapter 21). It is appropriate to confirm the presence of spherocytes by means of the osmotic fragility test and also to attempt to establish the familial nature of the illness by studying family members. Some unusual causes of spherocytosis may need to be considered if family studies provide no insight; immunohemolytic anemia may be associated with spherocytosis and is occasionally associated with a negative Coombs' reaction (page 913). Exposure to chemical or infectious agents producing spherocytosis may not always be easy to establish.

*Those with other specific morphologic abnormalities of erythrocytes.* The significance of various types of poikilocytes was discussed in a previous section (page 733) and does not need to be recapitulated in detail. Some poikilocytes, eg, elliptocytes and sickle cells, are virtually pathognomonic findings. Others, such as extensive red cell fragmentation, identify a category to which several diseases belong, as discussed in Chapter 28.

*Those with no specific morphologic abnormalities and a negative reaction to Coombs' test.* With these patients, a battery of screening tests should be performed, including hemoglobin electrophoresis (page 805), the heat denaturation test for unstable hemoglobin disease (page 808), the ascorbate-cyanide test (page 736), spot tests for deficiencies of pyruvate kinase (page 773) and glucose-6-phosphate dehydrogenase (page 788), and a screening test for paroxysmal nocturnal hemoglobinuria (page 961).

all of these procedures yield normal results,

making the diagnosis is likely to be difficult. One of the rarer erythrocyte enzyme deficiencies (Chapter 22) is possible, but these can be established only by specific assay.

## Therapy

Precise management of hemolytic anemia depends on the diagnosis. Thus, an attempt must be made immediately to ascertain the cause of the hemolytic anemia and to treat it if possible. Further exposure to any possible chemical, drug, or other etiologic agent must be stopped, or, if a bacterial agent is the cause, the infection should be treated specifically. Appropriate treatment of patients with "symptomatic" hemolytic anemias will need to be considered according to the nature of the underlying disease. Other more or less specific modes of therapy will be considered in sections dealing with specific entities. There are, however, certain generalizations that apply to a large proportion of the hemolytic diseases. These will be considered here.

A patient having an acute attack of hemolysis is treated by the use of appropriate measures to relieve shock, if present, maintain fluid balance, and allow renal repair, if the kidneys have been damaged, as fully outlined elsewhere. Blood transfusions, so useful in acute anemia of other types, must be employed with caution in hemolytic anemias, for, even when great care is taken in matching the blood, destruction of the transfused blood with an increase in the burden on the excretory organs and sometimes with ensuing thromboses may occur. Nevertheless, when blood destruction is rapid, the dangerous consequences of shock can only be met by administration of adequate amounts of blood. The presence of antibodies makes matching of blood difficult. Whenever possible, the patient's blood should be genotyped before the first transfusion and the specificity of his antibodies determined. Blood homologous as to ABO and Rh blood groups should be matched with that of the patient and the best match used. It should be ascertained that the recipient's serum does not contain hemolysins against a prospective donor's

bating them in a test tube at 37° C for one hour. In spite of all such precautions, transfusion may nevertheless accelerate hemolysis. In such cases, exchange transfusion may be required.

Since the spleen often is a major site of red cell destruction in hemolytic disorders, *splenectomy* may bring about relief or improvement in these illnesses. There is considerable variation in the response to splenectomy in the various hemolytic disorders. As a general rule, mildly damaged red cells are removed predominantly by the spleen, whereas more severely injured cells are destroyed by many parts of the RES, especially the liver (page 204). Therefore, patients with diseases associated with mild red cell defects are the ones most likely to respond to splenectomy.

The best and most consistent response to splenectomy occurs in persons with hereditary spherocytosis. Following this operation, all signs of hemolysis disappear although spherocytosis is unaltered (Chapter 21). A similarly excellent response has been observed in patients having hereditary elliptocytosis with an associated hemolytic process (page 761). Anemia associated with certain of the red cells' enzymatic deficiencies may lessen following splenectomy, but the response is only partial, and continuing signs of hemolysis are to be expected, such responses have been observed in patients with deficiencies of pyruvate kinase, hexokinase, or glucose-phosphate isomerase (Chapter 22). In unstable hemoglobin disease (Chapter 24), patients with mild to moderate disease improve after splenectomy, but those with severe disease do not.

In persons with immunohemolytic anemia, splenectomy may be effective not only because the spleen is a site of erythrocyte destruction but also because it may be a source of antibody. In general, patients with warm antibodies are more likely to respond than those with cold antibodies, patients with splenomegaly respond better than those without a palpable spleen, and those with incomplete antibodies, especially if present in relatively small amounts, are more likely to respond favorably to splenectomy than those

with complete agglutinins or complement-fixing antibodies. Although these generalizations are helpful, it nevertheless remains true that the results of splenectomy are quite unpredictable. This has led to efforts to develop methods for assessing the erythroclastic function of the spleen in the individual patient. Such methods are based on the injection of <sup>51</sup>Cr-labeled erythrocytes and monitoring the radioactivity over the spleen and liver with a unidirectional scintillation counter. Excessive splenic sequestration suggests that the spleen is playing a major role in hemolysis and that its removal may be beneficial (Chapter 27).

*Steroid hormones* are of great value in therapy of patients with certain forms of immunohemolytic anemia. Principles regarding their use are discussed in Chapter 27.

In patients with chronic hemolytic disorders, *folic acid* may sometimes be useful to prevent megaloblastic crisis (Chapter 14). A dose of 0.15 to 0.3 mg per day is ample for this purpose. Such therapy is particularly indicated in patients with severe, continuing hemolysis, in those subsisting on marginal diets, and in those who become pregnant.

## Acquired Hemolytic Anemia Resulting from Infections, from Chemical Agents, and from Physical Agents

The great majority of cases of acquired hemolytic anemia result from either antibodies directed against the red cell (Chapter 27), fragmentation of the erythrocyte (Chapter 28), or paroxysmal nocturnal hemoglobinemia (Chapter 29). There remains a group of hemolytic disorders, most of which are relatively uncommon, that are associated with infectious, chemical, or physical agents that damage the red cell directly. These disorders will be discussed in this section.

### Infectious Agents

Infectious agents may induce hemolytic anemia in several ways: (1) they may precipitate a crisis in a preexisting, compensated

hemolytic state (page 723); (2) certain viral and mycoplasma microorganisms appear to bring about the formation of hemolytic auto-antibodies (Chapter 27); (3) infection may precipitate hemolysis in patients with glucose-6-phosphate dehydrogenase deficiency (Chapter 23); and (4) the infectious agent may damage the erythrocyte directly. Only the last category will be considered here, as well as some instances in which pathogenesis is obscure.

## Malaria

Malaria is an acute, chronic, or recurrent febrile disease caused in man by four species of *Plasmodia*: *P. vivax*, *P. falciparum*, *P. malariae*, and *P. ovale*. Another species, *P. knowlesi* causes malaria in rhesus monkeys. These protozoan microorganisms are capable of parasitizing erythrocytes and certain other body tissues. Malaria is spread by mosquitoes of the genus *Anopheles*, and its semitropical and tropical endemic distribution corresponds to the distribution of this vector. Endemic areas no longer exist in the USA, although sporadic cases and small epidemics have been associated with Armed Forces personnel returning from endemic areas. The major clinical manifestations of the illness vary with the species and strain of *Plasmodium*, but the most prominent features are recurrent paroxysms of chills and fever associated with malaise, headache, and other systemic symptoms. Jaundice and hepatosplenomegaly may develop late in the course of the illness.

Mild anemia is a common sign of malaria. More severe anemia (VPRC less than 0.35 l/l) is observed in approximately 20% of patients with *falciparum* malaria.<sup>150</sup> The anemia appears to be a direct consequence of red cell invasion by the parasite. Erythrocyte life span is shortened considerably,<sup>150</sup> osmotic fragility is increased,<sup>177</sup> and haptoglobin disappears from the serum.<sup>147</sup> The hemolysis is accounted for in part by splenic removal and destruction of parasitized cells.<sup>176</sup> In addition, "pitting" of the parasite from the erythrocyte may occur, the cell being damaged in the process and consequently becoming more

susceptible to subsequent destruction. A lesion of nonparasitized erythrocytes, detected by means of scanning electron microscopy, was interpreted to be a cellular "scar" formed during the "pitting" process.<sup>142</sup> Such a lesion might explain the increased osmotic fragility and increased susceptibility to destruction of nonparasitized cells.

Anemia in malaria may also result in part from relative marrow failure (page 717), for the percentage of reticulocytes, which tends to be low during active infection, increases transiently following effective treatment. In *vivax* malaria, however, this phenomenon may be explained in part by an increased affinity of the organism for reticulocytes.<sup>182</sup>

The most serious hematologic complication of malaria is acute intravascular hemolytic anemia (*blackwater fever*), which occurs as a rare event in the course of infection by *P. falciparum*. The clinical manifestations are fulminating, the intravascular hemolysis being associated with prostration, vomiting, chills, and pyrexia. Hemoglobinemia, methemalbuminemia, hemoglobinuria, and hyperbilirubinemia are consistent features. In the most severe episodes, acute oliguric renal failure supervenes.

The pathogenesis of blackwater fever remains uncertain, and the present-day rarity of the disease has made adequate study by modern techniques difficult. Blackwater fever does not appear to reflect an unusual degree of parasitemia; in fact, characteristic ring forms often are absent from erythrocytes during the attack.<sup>156</sup> Europeans who have had repeated attacks of malaria and who have taken quinine irregularly have been the chief victims of the complication.<sup>146,156</sup> Often the disease appears to have been precipitated by taking quinine (Fig. 20-5), perhaps suggesting an immunologic reaction of the "innocent bystander" variety (page 917). Evidence supporting an autoimmune explanation for blackwater fever is largely indirect<sup>183</sup>; most attempts to demonstrate red cell antibodies have failed, but a few instances associated with positive reactions to Coombs' tests have been reported.<sup>141</sup> Some episodes thought to represent blackwater fever may have resulted from the use of primaquine-like drugs

*verruca peruana*, a benign condition characterized by wart-like lesions on the skin.<sup>175</sup> With Oroya fever, it is classified as *Carrión's disease*, named after the student who lost his life while investigating it.<sup>175</sup> Patients with *Bartonella* infection can be treated effectively with penicillin and other antibiotics.

*Bartonella muris* is found in rats (Fig. 45-1, page 1409). Anemia due to related organisms has been described in the dog and other animals as well as in rats. An interesting feature of the infection in animals is that anemia rarely occurs in the normal animal; instead, it develops in splenectomized rats<sup>171</sup> or in dogs receiving a deficient diet or deprived of plasma substances by plasmapheresis.<sup>165, 171</sup> It has been clearly demonstrated in the animal studies that the anemia is due to blood destruction.<sup>182</sup>

### *Clostridial Sepsis*

*Clostridium welchii* (*Cl. perfringens*) septicemia, usually following septic abortion,<sup>52, 166</sup> but sometimes occurring in association with a diseased biliary tree,<sup>144</sup> or leukemia,<sup>148</sup> quite regularly produces profound hemolytic anemia. Signs of intravascular hemolysis are prominent, and many microspherocytes are found in the blood. The hemolysis probably results from the elaboration of clostridial  $\alpha$ -toxin,<sup>161</sup> a lecithinase that acts upon the erythrocyte membrane lipids to form highly lytic lysolecithins.

### *Other Bacterial Infections*

Only a few instances of hemolytic anemia have been encountered in most other bacterial infections. Hemolysis has been reported in children suffering from streptococcal, staphylococcal, or pneumococcal septicemia or endocarditis.<sup>41, 149, 152, 157, 169</sup> Hemolytic anemia could be induced by intradermal injections of living pneumococci in rabbits.<sup>178</sup> Hemolytic anemia and thrombocytopenia were noted in a patient with meningococcemia.<sup>170</sup>

Certain gram-negative bacillary infections have occasionally been associated with

hemolytic anemia. Intravascular hemolysis with hemoglobinuria has been observed in patients with *cholera*.<sup>155</sup> Hemoglobinuria has been reported as occurring in patients with typhoid fever,<sup>172</sup> and a milder hemolytic state is a well-known, though uncommon, complication of this illness.<sup>145, 161, 172</sup> Hemolysis has only rarely been reported with other *Salmonella*<sup>153, 154</sup> infections or with *E. coli* infections.<sup>160</sup> The hemolytic anemia noted in patients with *H. influenzae* meningitis was ascribed to anti-erythrocyte antibodies in the rabbit antisera used in treatment, rather than to the direct effects of the microorganism.<sup>167</sup>

Severe hemolytic anemia has been observed occasionally in patients with *tuberculosis*, but the pathogenesis is obscure. In several of such patients, the tuberculosis was in the generalized, miliary stage<sup>41, 163</sup> or involved the spleen,<sup>158, 159</sup> but in others it was confined to the chest.<sup>166, 179</sup>

Hemolytic anemia has been noted in a patient with relapsing fever, caused by the spirochete *Borrelia recurrentis*.<sup>143</sup>

## **Chemical Agents, Drugs, and Venoms**

### *Oxidant Drugs and Chemicals*

A number of chemical agents can bring about the oxidative denaturation of hemoglobin, leading to the sequential formation of methemoglobin, sulfhemoglobin, and Heinz bodies (page 204). In some cases, the chemical itself acts as an oxidizing agent, but, more frequently, it interacts with oxygen to form free radicals or peroxides. These, if produced in quantities too great to be detoxified by the glutathione-dependent reduction system (page 103), are the substances that damage hemoglobin and other cellular structures.

Individuals deficient in glucose-6-phosphate dehydrogenase (G6PD) or other components of glutathione-dependent detoxification processes (Chapter 23) are particularly sensitive to the hemolytic effects of "oxidant" compounds (Table 23-2, page 785). It is also true, however, that some of these agents are powerful enough to overcome the defense mechanisms of apparently normal erythro-

cytes. Others produce hemolysis if given to normal subjects in higher than usual doses or if renal failure leads to unusually high blood levels

From reports submitted to the AMA registry on adverse drug reactions, the most common drugs and chemicals implicated in hemolysis in normal subjects appear to be naphthalene (mothballs), nitrofurantoin (Furadantin), salicylazosulfidine (Azulfidine), sulfamethoxypyridine (Kinex), aminosalicilic acid, and sodium sulfoxone.<sup>202</sup> Data from other sources give evidence of the relatively high frequency of reactions to various sulfonamide compounds.<sup>221-231</sup> Other agents reported to cause "oxidative" hemolysis in apparently normal subjects include phenacetin,<sup>219</sup> sulfones,<sup>219-223</sup> phenylsemicarbazide,<sup>231</sup> resorcin,<sup>217</sup> phenylhydrazine and its derivatives,<sup>201-203</sup> aniline,<sup>232</sup> hydroxylamine,<sup>231</sup> nitrobenzene,<sup>233</sup> phenol derivatives,<sup>216</sup> and potassium or sodium chlorates.<sup>211-224</sup>

Molecular oxygen may cause hemolysis under certain circumstances.<sup>230</sup> A mild hemolytic reaction was observed in an individual treated for stroke with oxygen at high pressure.<sup>235</sup> Over a six-day period following the exposure, the VPRC fell from 0.48 to

0.35 l/l, the reticulocytes increased from 0.5 to 4.6%, and the bilirubin rose to 1.6 mg/dl. Hemolysis also has been induced in mice by exposure to oxygen, and the intensity of the reaction was greatly exaggerated in vitamin E-deficient animals (Chapter 4). In normal human subjects only four hours of exposure to 100% oxygen induced an increase in plasma hemoglobin levels to about 25 mg/dl, and abnormalities in erythrocyte osmotic fragility were detected.<sup>230</sup> It is likely that the toxic effects of oxygen are related to the generation of  $H_2O_2$ ,<sup>235</sup> and the peroxidation of membrane lipids.<sup>214</sup>

### Chemicals Producing Hemolysis by Nonoxidative Mechanisms

*Arsine* (arsenitretted hydrogen) is the name given to a highly toxic mixture of gases incorporating arsenic and hydrogen, of which the most common is  $AsH_3$ . Arsine has certain industrial uses, eg, in the manufacture of bleaches, of fertilizers,<sup>219</sup> and in tin-mining. It also evolves whenever nascent hydrogen is generated in the presence of arsenic, as can occur unsuspectingly when acids contact certain ores and waste materials containing metals and traces of arsenic.<sup>226</sup> The impor-

# PLATE XI

INEZ DEMONET

tant acute toxic effects of arsine include renal and hepatic damage and acute hemolytic anemia, which begins within a few hours of exposure. Signs of intravascular hemolysis are prominent, and severe anemia may develop in the absence of morphologic changes in the red cells. Leukocytosis is a usual feature. A mortality rate of 22.5% was recorded in the past.<sup>204</sup> A more chronic form of arsine poisoning occurring in gold-refiners was associated with severe hemolytic anemia, prominent stippling, erythroblastosis, and rapid recovery when exposure was interrupted.<sup>205</sup> The way in which arsine damages erythrocytes is poorly understood.<sup>226</sup>

Hemolytic anemia can occur as a result of the direct effects of *inorganic copper* on the red cell. Such episodes have been noted rarely in persons<sup>207,215</sup> and animals<sup>218,245</sup> exposed to toxic amounts of copper sulfate. Copper also has been implicated in hemolytic episodes following hemodialysis.<sup>228,233</sup> In addition, hemolytic anemia occurring during the course of Wilson's disease results from the release of large amounts of inorganic copper into the blood stream.<sup>213</sup> A number of abnormalities can be induced by exposure of erythrocytes to copper salts *in vitro*,<sup>213,236</sup> including increased autohemolysis, thermolability of hemoglobin, decreased glutathione levels, Heinz-body formation, and decreased activity of various enzymes associated with the hexose monophosphate shunt. The relation of these abnormalities to hemolysis *in vivo* is unclear, however.

Hemoglobinuria and even death from renal failure have been observed in association with transurethral resection of the prostate, apparently as the result of penetration of the irrigating fluid, *distilled water*, into the blood stream via lymphatic and venous channels opened by the operation.<sup>229</sup> The entry of more than 0.6 liter of water into the circulation will produce hemoglobinemia and hemoglobinuria as a result of osmotic hemolysis. This is probably the cause of the hemolysis noted in survivors of near drowning in fresh water.<sup>241</sup> In such situations the normal protective mechanisms (page 205) are overwhelmed.

Hemolytic anemia resulting from drug-induced immune reactions is discussed in Chapter 27 (page 916).

### Venoms

Fewer than 20 cases of hemolytic anemia have been reported in association with *spider bites*. In most instances, the spider has not been specifically identified, but clinical and epidemiologic data strongly implicate the brown recluse spiders, *Loxosceles reclusus* and *Loxosceles laeta*,<sup>239</sup> which inhabit South America and the Central and Southern United States. Their initially painless bite develops into a painful, edematous, necrotic lesion that may progress to an extensive, slowly healing, gangrenous process (necrotic arachnidism). In a minority of patients, typical, acute, intravascular, hemolytic anemia develops within several hours to five days after being bitten. Hemoglobinuria and severe anemia are characteristic findings; spherocytes, anisopoikilocytosis, stippling, and leukocytosis are found in the blood; and mechanical and osmotic fragility of the erythrocytes is increased. The hemolytic episode subsides spontaneously in about one week. The nature of the hypersensitivity of the patients developing the hemolytic reaction has not been determined; in at least one patient the possibility of glucose-6-phosphate dehydrogenase deficiency was excluded.<sup>239</sup>

*Snake venoms*, especially cobra venom, hemolyze red cells *in vitro*, the hemolytic activity depending upon two constituents, a phospholipase and a basic protein called "direct lytic factor."<sup>206</sup> Hemolytic anemia is a relatively uncommon manifestation of cobra bites, possibly because critical amounts of venom are not often injected into the blood stream. Of 47 patients bitten by a cobra, only 6 developed systemic toxicity. Three of these developed a mild to moderate hemolytic anemia characterized by a fall in blood hemoglobin concentration of 3 to 4 g/dl, reticulocytosis, hyperbilirubinemia, and leukocytosis.<sup>242</sup> No signs of intravascular hemolysis were observed. On the other hand, red cell abnormalities were found in all of a group

of five patients who were bitten by vipers or cobras in India.<sup>240</sup> Spherocytes were prominent, comprising 30 to 50% of red cells by three to four days after the patients were bitten. The plasma hemoglobin ranged from 0.02 to 0.06 g/dl, and hemoglobinuria occurred in two of the patients. Other abnormalities included falsely positive reactions to Coombs' tests, acanthocytosis, the presence of Heinz bodies, and erythroblastosis. Blood hemoglobin levels decreased to as low as 10 g/dl.

Hemolytic reactions to *bee stings* appear to be very rare. In one instance, a three-year-old child who was stung 200 to 300 times by honey-bees died following the development of intravascular hemolysis and oliguric renal failure.<sup>203</sup>

## Physical Agents

### Thermal Injury

Acute hemolytic anemia has been observed following extensive thermal burns.<sup>237,243</sup> Signs of intravascular hemolysis are associated with schistocytes and spherocytes in the blood and increased osmotic and mechanical fragility of the erythrocytes.<sup>243,246</sup> The hemolysis occurs during the 24- to 48-hour period following the burn,<sup>246</sup> and the severity of the reaction is related to the area of body surface affected. Thus, hemoglobinuria was found in 11 of 14 moderately to severely burned patients, and in most of these more than 15% of the body surface was involved.<sup>243</sup> In another study, hemolysis was apparent in patients with third-degree burns affecting more than 20% of the body surface.<sup>225</sup> As much as 30% of the circulating red cell mass may be destroyed in a two-day period in severely burned individuals.<sup>210,247</sup> Following the acute hemolytic process, anemia develops and may last for many weeks.<sup>231</sup> After the first 48 hours, however, signs of hemolysis are not prominent, and it is likely that these later stages of the anemia of thermal injury are a form of the anemia of chronic disorders (Chapter 18).

The acute hemolytic reaction probably re-

sults from the direct effects of heat on erythrocytes. When red cells were heated *in vitro* to temperatures greater than 47° C, irreversible morphologic and functional abnormalities occurred, the severity of which was related to the temperature and the duration of exposure.<sup>220,227</sup> The major alterations were fragmentation of the cells and the development of spherocytes, accompanied by an increase in osmotic and mechanical fragility. Furthermore, when such cells were injected into experimental animals, prompt hemoglobinemia and hemoglobinuria were observed with selective removal of the abnormal cells within a few hours.<sup>220</sup> With <sup>51</sup>Cr, it could be demonstrated that mildly heat-damaged erythrocytes are removed predominantly by the spleen, but, with greater degrees of damage, the isotope accumulates in the liver.<sup>227,248</sup>

### Ionizing Irradiation

Very high doses of total body irradiation (180 to 600 r) resulted in reduced erythrocyte survival in dogs.<sup>241</sup> This effect did not seem to result from direct radiation-induced damage to red cells, since reduced survival of even donor cells occurred in previously irradiated animals. In *in vitro* studies, red cells were found to be very resistant to radiation damage, doses in the range of 20,000 r being required to produce detectable effects.<sup>212</sup> However, *in vivo* radiation in mice resulted in a tendency of erythrocytes to agglutinate spontaneously in saline solution and to undergo hemolysis in acidified serum.<sup>222</sup> Despite these observations, no clear evidence that irradiation induces hemolytic anemia in man has been presented.

## Acquired Hemolytic Anemia Associated with Hypophosphatemia

Severe spherocytic hemolytic anemia (VPRC 0.25 l/l, reticulocytes 8%, t<sub>1/2</sub> Cr 4.5 days) was detected in a patient with profound hypophosphatemia<sup>15</sup> (serum phosphorus, less

than 0.1 mg/dl). Increased rigidity of the erythrocytes was associated with an 11 to 30% reduction in important intracellular phosphorylated compounds, principally ATP and 2,3 DPG. All of the abnormalities returned to normal after parental phosphate administration.

### Hereditary Spherocytosis (HS)

#### Definition and History<sup>35,97</sup>

Hereditary spherocytosis is characterized by a variable degree of anemia, splenomegaly, spherocytosis, and increased osmotic fragility of the red corpuscles, as well as by jaundice, often of mild degree and unaccompanied by bile in the urine (acholuric). HS is inherited as an autosomal dominant trait, but the clinical manifestations may be so mild that the disease may sometimes not be recognized even until late adult life and the true extent of familial involvement may be appreciated for the first time only after thorough examination of family members has been carried out, rather than from their history alone. Earlier commonly used synonyms, *congenital hemolytic jaundice* and *chronic familial jaundice*, emphasize the prominence of the jaundice in many HS patients.

The earliest observations concerned with hemolytic anemias, including HS, were described in Chapter 20 (page 718). The studies

THE pathogenesis and classification of hemolytic anemias of various kinds were discussed in Chapter 20. Here those conditions in which the cause of the increased red cell destruction has been found to reside in the red cell membrane will be considered. Of these, hereditary spherocytosis is the prime example, but several less common conditions will also be discussed. Noteworthy is the fact that all of these disorders are characterized by observable morphologic abnormalities of the red cell.

of Haden<sup>18</sup> and of Castle and Daland<sup>14</sup> subsequently drew attention to the possibility that a structural abnormality is the underlying defect in HS. The relation of the spleen to the manifestations of this disease and the reasons for the curative role of splenectomy were clarified by the studies of Young and his associates<sup>112</sup> and of other investigators, as will be described below (page 757).

### Prevalence

HS probably is the most common of the hereditary hemolytic anemias among people of Northern European descent. In the United States the incidence is approximately 220 per million.<sup>79</sup> On the basis of the study of family trees extending through three or four generations<sup>31,43,111</sup> it is clear that the HS gene is transmissible through either parent<sup>71,87</sup> but penetrance may be incomplete, as is ascertainment.<sup>79</sup> Consequently, somewhat fewer than half the siblings have been found to be affected (0.45).<sup>72,79</sup> Homozygosity for the trait, never certainly established, was presumed in a family in which all 13 children were affected; 9 of these children manifested physical or mental retardation.<sup>8</sup> Sporadic cases, with both parents unaffected, are rare.<sup>31,87,111</sup>

HS is uncommon in Negroes,<sup>66</sup> but has been found even in African Bantu.<sup>75</sup> Males and females are affected equally. The condition has been recognized at all ages, in the form of severe jaundice at birth,<sup>71,91,109</sup> and even in old age (77 years).<sup>87</sup> The extremes are unusual, however. In a series of 28 cases,<sup>111</sup> anemia or jaundice was first detected at age 10 or younger in 8 patients and between the ages of 10 and 45 years in 15, the age range of the remaining 5 patients having been from 47 to 54 years.

### Symptomatology

The symptoms are those characteristic of chronic congenital hemolytic anemia (Chapter 20, page 722), but they vary greatly, both in regard to their time of onset and their severity. They are most often first noticed in

childhood or adolescence; in these young subjects the disease is likely to be more severe than in persons in whom it is first detected later in life. How much this disease may vary in severity is indicated by a study of 68 out of 161 members of a family comprising three generations; 11 of the 68 showed all the manifestations of the disease, 34 had the disease in a well-compensated form without anemia, in 13 the manifestations were mild, and 10 were completely healthy.<sup>43</sup> Because the signs of HS may be subtle, a study based only on family history, that does not include examination of the relatives of a patient, cannot be regarded as being negative as far as inheritance of the disorder is concerned.

Icterus usually is not intense, and is said to increase with fatigue, cold, emotion, or pregnancy. There may be no detectable jaundice despite other signs of active hemolysis,<sup>43,71,72,97</sup> or there is a constant sallow complexion, but even when icterus is well marked the patients are generally "more yellow than sick." The jaundice, no matter how intense, is not accompanied by itching of the skin, bradycardia, or xanthoma. Once severe jaundice and anemia have developed, complete spontaneous remission is unusual.<sup>96</sup>

From time to time the jaundice may deepen and the anemia increase. Abdominal pain, vomiting, tachycardia, and fever may be associated.<sup>31</sup> In addition, at any time, even for the first time in late adult life, there may be a sudden, acutely developing illness, the "*crise de déglobulization*" (Chapter 20, page 723). Such episodes<sup>31,90</sup> had been attributed to a sudden acceleration of blood destruction, but Owren,<sup>82</sup> studying four cases occurring in members of the same family, was impressed by the disappearance of reticulocytes from the blood, and the presence of leukopenia, thrombocytopenia, and acute aplasia of the erythropoietic tissue in the bone marrow (Fig. 20-1). As discussed in Chapter 20, such *acute erythroblastopenia*<sup>41</sup> or aplasia may develop at the same time in several affected members of a family.<sup>28,47,73</sup> The crisis may last from 5 to 12 days.

Symptoms of *biliary tract disease* may first bring the patient to the physician. Cholelithia-

sis has been found in 43<sup>4</sup> to 85%<sup>111</sup> of the patients and has been described as present even in patients as young as 3 years of age.<sup>42</sup> An uncommon complication, which may nevertheless be the chief complaint, is chronic leg ulcer<sup>38,95</sup> (Chapter 20, page 723). Sometimes chronic dermatosis<sup>13</sup> and pigmentation (Fig. 21-1) may be the only indications of a healed chronic ulcer.

The *spleen* is almost always enlarged when the disease is active and may be huge. In extensive family studies, the spleen was found to be palpable in 75<sup>71</sup> to 82%<sup>111</sup> of affected individuals. Its size has not been found to be related to the severity of the disease.<sup>71</sup>

The liver may not be palpable or it may extend 1 to 3 cm below the costal margin. The finding of an exceptionally large liver should arouse suspicion of a complication or an error in diagnosis.

Nosebleeds are common in childhood, but hemorrhage from other parts of the body, as in Banti's syndrome or in cirrhosis of the liver, does not occur. Sometimes the lymph nodes may be enlarged.<sup>31</sup> Neural symptoms have been reported,<sup>24</sup> but they must be exceedingly rare.

The tower skull ("Turmschädel") is the most common skeletal abnormality that may be associated with HS,<sup>111</sup> and thickening and striation of the frontal and parietal bones may be noted on x-ray examination.<sup>13</sup> Changes in the bones that are similar to those present in sickle cell anemia and thalassemia, though less marked, may be seen. X ray may reveal masses of heterotopic bone marrow (page

757) alongside the vertebral column, and these may be mistaken for tumors.<sup>21,50,54</sup>

More than two dozen different congenital anomalies have been described in patients with HS, including prominent eyes,<sup>31</sup> epicanthus, persistent pupillary membrane, abnormally wide root of the nose, persistence of deciduous teeth in adults, misplacement of permanent teeth, palatal deformities, polydactylia, and brachydactylia.<sup>43,51</sup> It is not certain, however, that the frequency of these anomalies exceeds that in the population at large.

If symptoms commence in childhood, growth may be impaired.<sup>31,43</sup> Infantilism may occur<sup>8</sup> and other endocrine disorders have been observed.<sup>41</sup>

## Laboratory Manifestations

### The Blood

Hemoglobin levels between 9 and 12 g/dl are most common, but anemia may not be present, or it may be quite severe. A rapid fall to 3 or 4 g/dl may occur during a crisis, and, even in the absence of anemia, hemoglobin values as low as 6 g/dl may be observed and may be maintained for a long time. The reduction in red cell count, hemoglobin level, and volume of packed red cells may or may not be proportional. MCV may be normal, increased, or greatly decreased. In a series of 76 affected, nonsplenectomized individuals the MCV was found to be  $83 \pm 8.5$  fl.<sup>72</sup> Values between 77 and 87 fl are common, but the MCV may be as low as 62 fl or as high as 125 fl. Macrocytic anemia is more likely to occur in subjects with very severe anemia and pronounced reticulocytosis. Variations in MCH usually correspond to changes in volume, but, characteristically, the MCHC is high (37 to 39 g/dl) (page 119).

Variation in the size of the red corpuscles and the presence of macrocytes have even led to confusion of HS with pernicious anemia in some instances. The mean diameter of the red cells is reduced, owing to the presence of round, fully hemoglobinized cells of small

Fig 21-1. Marked pigmentation of the skin about the ankles in a patient with hereditary spherocytosis

size (Fig. 21-2). These microspherocytes, even when as small as 4  $\mu\text{m}$  in diameter, show no central pallor because of their spherical rather than biconcave shape. Their diameter in stained smears averages 6.2 to 7.0  $\mu\text{m}$  (range 4.0 to 7.6  $\mu\text{m}$ ). In wet films of blood it also is below normal.

The unusual thickness<sup>18,96</sup> of the red corpuscles, 2.2 to 3.4  $\mu\text{m}$  instead of 2.0  $\mu\text{m}$  or less as in normal blood<sup>103</sup> (Fig. 21-3), accounts for the low mean cell diameter despite normal or only slightly reduced MCV. The degree of spherocytosis varies from patient to patient.

*Reticulocytes* are characteristically increased in number. Values between 5 and 20% are common, but they may be as high as 50 and even 92%,<sup>5</sup> or as low as 2%. In a series of 76 affected nonsplenectomized members of a family of 180, the mean reticulocyte count was  $9.9 \pm 4.9\%$ .<sup>71</sup> Polychromatophilia often will be observed in variable degree, as well as occasional normoblasts and micronormoblasts. During recovery following a crisis, such signs of active erythropoiesis are particularly prominent. Poikilocytosis is rarely very marked, although structures suggestive of fragmented red corpuscles may be seen.

The *fragility* of the red corpuscles in hypotonic saline solutions is increased in typical

Fig 21-3. Diagram representing cross section of erythrocytes in different clinical conditions. D refers to mean diameter, T means thickness and V means corpuscular volume (From Haden,<sup>49</sup> courtesy of the author and American Journal of Medical Sciences)

cases. The saline concentration at which hemolysis begins ranges from about 0.51 to 0.72 g/dl and may be as high as 0.87 g/dl. Hemolysis may be complete at the concentration where it normally commences. If the amount of hemolysis in various strengths of

Fig. 21-2 Blood smears from two patients with hereditary spherocytosis. There were many more spherocytes (the small, round, dark cells) in the smear on the left than in that on the right. Note the lack of poikilocytosis (Wright's stain,  $\times 800$ )

saline solution is plotted as a curve (Fig. 20-4, page 734), it may be found that the curve of hemolysis is normal in shape but shifted to the left; it may be "tailed" with only a small proportion of the red corpuscles hemolysing in saline concentrations greater than 0.45 g/dl<sup>25</sup>; or increased osmotic fragility may not be demonstrable until after 24-hour incubation of the cells.<sup>110</sup> There is no correlation between the degree of anemia and the fragility of the corpuscles, but osmotic fragility, measured under controlled conditions, was shown to be a precise measure of the degree of spherocytosis at the time of exposure to the hypotonic medium.<sup>14,37</sup> Osmotic fragility may be only minimally abnormal during an aplastic crisis.<sup>56</sup>

Mechanical fragility is greater than normal.<sup>111</sup> With rare exceptions,<sup>57,68,113</sup> the spontaneous autohemolysis, at 37° C, of sterile blood of HS patients occurs sooner and in greater degree than does the blood from normal persons<sup>92</sup> (10 to 50% instead of the normal 4%) or blood from patients with autoimmune hemolytic disease, except at times of very active blood destruction.<sup>111</sup> The addition of glucose or of ATP markedly reduces the degree of autohemolysis.<sup>92</sup>

Reaction to the Coombs' test usually is negative.<sup>111</sup> Reported positive reactions, when not attributable to the use of inadequately absorbed rabbit serum or inadequate characterization of the tested cases, may be explained, at least in some instances, by antibody development superimposed upon the original congenital disease.<sup>28</sup> If the reticulocyte count is high, a falsely positive reaction to Coombs' test may be due to the transferrin bound to the reticulocytes (page 160). Only minimal and irregular deviations in the activity of the enzymes of glycolysis are found.<sup>80</sup>

The number of leukocytes is usually normal or only slightly increased, but in an aplastic crisis it may be decreased and after a crisis there is marked leukocytosis and a "shift to the left." During the chronic stage of anemia, the numbers of lymphocytes, plasma cells, and basophils may be increased.<sup>43</sup> The platelet count usually is within

the normal range, although it may be somewhat increased or, more rarely, moderately reduced.

Serum bilirubin (indirect) is increased ( $1.6 \pm 1.1$  mg in one large series of cases<sup>72</sup>). (Fig. 20-3, page 728.) The icterus index may be as high as 100, but values of 15 to 30 are more common.

The plasma or serum iron value may be normal or increased.

### Urine

The urine may or may not contain increased amounts of urobilinogen, but bile pigments and bile salts are absent. Hemoglobinuria is very unusual. The stools contain excessive quantities of urobilinogen, as much as 5 to 20 times the normal.<sup>55,84</sup>

### Bone Marrow

In the bone marrow, erythropoietic hyperplasia of the normoblastic type is found. Normoblasts may comprise 25 to 60% of all the nucleated cells, and many mitotic forms are evident.<sup>69</sup> In the absence of complicating folate deficiency (page 579), megaloblasts of the type seen in pernicious anemia are not found, and the giant, abnormal leukocytes are also lacking.<sup>69</sup>

### Diagnosis

The presenting clinical picture may suggest a great variety of disorders that are characterized by jaundice,<sup>100</sup> fever, abdominal complaints, splenomegaly (Chapter 45), or anemia. Diagnosis depends on (1) establishing that hemolytic disease is present: anemia (usually), reticulocytosis, splenomegaly, unconjugated bilirubinemia and increased urobilinogen in the urine and stools; (2) detecting spherocytosis by examining the blood smear and measuring osmotic fragility; (3) excluding the possibility of other causes of spherocytosis; and (4) establishing the familial character of the condition.

The microspherocytosis is striking and the

cells are more uniform than those noted in immunohemolytic anemia or in other forms of hemolytic anemia that may be associated with spherocytosis, such as that following damage to the erythrocyte by chemical, infectious, or physical agents (Chapter 20). However, when the anemia is severe, macrocytosis may be marked. Nevertheless, there should be no confusion with pernicious anemia because HS patients usually are younger than pernicious anemia subjects and they do not have achlorhydria or neural involvement. Furthermore, in pernicious anemia, the reticulocytes are normal in number as a rule, except during the response to therapy. However, megaloblastic anemia may develop in HS subjects as in persons with other chronic hemolytic disorders, probably because of increased folate utilization associated with the net increase in the rate of DNA synthesis as the result of the marked and continuous erythroid hyperplasia (Chapter 14).<sup>63</sup> Such folate deficiency is more likely to occur when the diet has been deficient, when the patient has had repeated pregnancies, or when liver disease is present.<sup>67</sup>

Doubt may arise if the fragility of the red corpuscles is not found to be increased.<sup>25,43 110,114</sup> The value of incubation of the cells under these circumstances has been mentioned. Unless the diagnosis is clear-cut, the patient should be studied in the manner already described (page 737) in order to exclude the possibility of various other causes of hemolytic anemia (Table 20-3, page 721). The manifestations of acquired forms of hemolytic anemia usually are more severe than those of the hereditary forms. If there is a family history of anemia, jaundice, and/or splenomegaly, the various hereditary non-spherocytic hemolytic anemias, thalassemia, sickle cell anemia, and other hemoglobinopathies must be considered. It should be borne in mind that appearance of symptoms late in life does not exclude HS (page 752) and that a family history without appropriate examinations is not to be trusted. Constitutional hyperbilirubinemia (Table 20-6, page 729) has been confused with hereditary spherocytosis.

## Complications

The frequency of biliary tract disease has been mentioned previously. So also has the rare occurrence of chronic leg ulcers, megaloblastic anemia, and various developmental anomalies. Gout has been observed.<sup>97</sup>

The discovery of gallstones in a young person should cause one to suspect the existence of HS. If HS is diagnosed, splenectomy must be performed before or simultaneously with cholecystectomy, since the bilirubinemia requires correction if the deposition of bilirubin salts is to be avoided. Secondary hemachromatosis has been observed<sup>3</sup> and primary carcinoma of the gallbladder was encountered at the unusually early age of 36 years in a patient with HS.<sup>49</sup>

## Treatment

HS is the one disorder in which splenectomy is associated with almost uniformly beneficial and lasting results. Splenectomy is followed in a few days by fading of the jaundice and a gradual rise in hemoglobin and VPRC to normal levels, which are reached in several weeks.<sup>93</sup> The reticulocytes decrease and other signs of accelerated erythropoiesis disappear. Red cell survival increases<sup>2</sup> but does not become entirely normal.<sup>15</sup> Microcytosis often persists and spherocytes usually are still found in the blood smear.<sup>111</sup> The corpuscular fragility usually is unaltered.<sup>97</sup> However, in some patients, the blood findings are modified in the direction of normal.<sup>104</sup> The platelet count usually rises following splenectomy. Leukocytosis, even to  $48 \times 10^9/l$ , follows splenectomy immediately and persists in moderate degree for a long time<sup>29</sup> after operation.

Splenectomy should be advised in any patient who has typical HS if he has been continuously anemic or gives a history of hemolytic or aplastic crises. The operative mortality in good hands is extremely low. The presence of cholelithiasis would indicate the need for splenectomy. Chronic leg ulcers may clear up only after splenectomy.<sup>95</sup> It is difficult to see what is to be gained by delay-

ing operation unless the patient is completely compensated and has always been symptom free. Even in such subjects, one cannot be sure that this good fortune will persist and, in fact, development of biliary tract disease is to be expected. Only in infancy should the operation be delayed since the risk of infection is greater in the first year of life than later.<sup>11</sup> However, splenectomy in children with this disease does not carry the high risk that has been claimed (page 360) and operation at four to five years of age has the advantage that impairment of growth and risks from crises or other complications are avoided.

The use of anticoagulants postoperatively to prevent thrombosis is unnecessary, in spite of marked postoperative thrombocytosis.

Cases have been reported in which the dramatic improvement that usually follows splenectomy did not occur. In such cases the correctness of the diagnosis must be questioned. Failure to relieve the jaundice and anemia also raises the possibility that accessory spleens were overlooked; however, there are but three well-documented instances of such a finding on surgical exploration.<sup>70</sup>

Other measures are of no value in this condition. Iron is contraindicated, vitamin B<sub>12</sub> and corticosteroids are not helpful, and folic acid is useful only when there is complicating folate deficiency<sup>71</sup> (page 579). Blood transfusions are usually unnecessary except in a crisis.

### Prognosis

The illness generally is more serious when symptoms appear in childhood than in later life.<sup>33</sup> Death may occur during a crisis. Repeated attacks may be associated with impairment of bodily and sometimes mental development; cardiac decompensation may occur and biliary tract disease may ensue.<sup>33</sup> Many patients, however, have attained an advanced age in spite of chronic anemia.<sup>96</sup> The histories of some patients<sup>19</sup> suggest that there may be prolonged spontaneous improvement without recurrence of jaundice until late adult life, but, usually, once jaun-

dice has set in, it does not clear up completely until after splenectomy.

### Pathology

The spleen is enlarged, weighing 1000 to 1500 g, and is usually easily removed at operation. Adhesions are uncommon. The cut surface is relatively dry, dark purplish-red in color, homogeneous in texture, and bulges slightly above the capsule. The malpighian bodies cannot be distinguished. Microscopically they are found to be small and widely separated. The pulp is a mass of closely packed red cells which distend, distort, and dilate it. By light microscopy the sinuses appear empty, but electron microscopy shows them to contain red cells the majority of which have lost their hemoglobin.<sup>78</sup> There may or may not be increased iron pigment.<sup>100</sup> Cordal macrophages are increased and show active erythrophagocytosis, as do the sinus endothelial cells.<sup>78</sup> Unlike the finding in the spleen of Banti's syndrome, there is no thickening of the trabeculae.

The liver is not enlarged in most patients, nor is it usually cirrhotic, but the quantity of iron pigment may be increased in the hepatic and the Kupffer cells, and bilirubin stones may be found in the gallbladder. The kidneys often show well-marked hemosiderosis and the lymph glands may also contain pigment.

The bone marrow is strikingly hyperplastic, dark red in color, and free from fat. The microscopic picture is that of marked erythroid hyperplasia (page 755). Heteropia of the bone marrow may be found in the renal pelvis<sup>29</sup> or along the vertebral column.

### Pathologic Physiology and Pathogenesis

The fact that the manifestations of HS are the consequence of an inherited trait whereby red corpuscles of unusual thickness closely approaching spheres in shape are produced<sup>13</sup> is central to an understanding of this disease. HS cells have a configuration similar to that assumed by red corpuscles when they are about to burst in hypotonic solutions of so-

dium chloride (Fig. 21-4).<sup>45</sup> The vulnerability of these cells to destruction, especially in the spleen, results in the manifestations of hemolytic disease and, because this destruction is extravascular, such manifestations as hemoglobinemia and hemoglobinuria almost never occur. Because the normal bone marrow in case of need is capable of increasing red cell production six- to eight-fold (Chapter 20), anemia may be minimal or even entirely absent; only under special circumstances, not well understood, does compensation for the increased rate of destruction become impaired and "aplastic" crises develop.

The inherent defectiveness of the HS erythrocyte is shown by the fact that the survival of HS cells is greatly reduced even when the cells are transfused to normal individuals; on the other hand, normal cells survive normally in the circulation of persons who have inherited HS.<sup>26</sup> Yet the shape of

the cells is not of itself responsible for their destruction. Thus, when two nonanemic patients with HS were phlebotomized until their cells became hypochromic and thin, the cells' life span in the circulation was not improved.<sup>22</sup>

As described in Chapter 3, the red corpuscle possesses an energy-dependent system of active cation transport that requires a continuous supply of glucose. Incubation of normal cells in the absence of glucose leads eventually to depletion of ATP and loss of the mechanisms whereby membrane impermeability to cations is maintained. This need for glucose makes red corpuscles vulnerable to sequestration.

In the HS cell, glycolysis is not defective, as was once assumed.<sup>65-66</sup> However, for two reasons the HS cell is especially vulnerable to the effects of sequestration; these are an increased rate of  $\text{Na}^+$  flux<sup>9,32,39,108</sup> and depletion of membrane lipids. The heightened influx of  $\text{Na}^+$  stimulates an usually latent ATPase system.<sup>77</sup> As a consequence, there is heightened breakdown of ATP and this provides energy for pumping the sodium out of the cell, liberates ADP and inorganic phosphate, and stimulates glycolysis. Because of the accelerated glycolysis, the changes associated with sterile incubation of normal red cells are exaggerated in HS.<sup>85</sup>

The increased  $\text{Na}^+$  flux, however, does not explain the accelerated destruction of HS cells *in vivo*. After splenectomy this defect persists, but the survival of the cells is essentially normal. This observation focused attention on the membrane and this in turn stimulated study of the membrane lipids. It was then found that the total lipid content of HS cells is lower than that of normal cells,<sup>68,88</sup> although the relative proportions of cholesterol and phospholipid as well as the various phospholipids are normal.<sup>45</sup> HS cells were shown to lose membrane lipids excessively during incubation *in vitro*.<sup>57,104</sup> The loss is less pronounced in the HS cells that circulate following splenectomy,<sup>19,88</sup> but the lipid content of such cells still is lower than that of cells from splenectomized normal persons.<sup>19</sup> The lipid depletion has been at-

Fig 21-4 Changes in the shape and measurements of the mean erythrocytes of normal blood on the addition of varying amounts of distilled water to the plasma (From Haden,<sup>44</sup> courtesy of the author and American Journal of Medical Sciences)

tributed to the greatly increased metabolic activity required for the accelerated pumping of sodium ions, this being associated with increased phospholipid turnover.<sup>57</sup> With the loss of lipid and, consequently, of surface area, HS red cells lose pliability and plasticity.

In the course of its normal life-span the red corpuscle must traverse slit-like stomas, some of which may be as small as 3  $\mu$ m. To accomplish this it must possess sufficient membrane surface area to undergo the extremes of deformation imposed by the circulation and yet resume its normal biconcave shape. Of the hazards of the circulation, the spleen is the most exacting and if the corpuscle is not easily deformable it may be trapped there.

Well before the membrane defect of the HS cell, as manifested by the sodium leak, was clearly identified and the lipid depletion of the HS membrane was demonstrated, Young et al,<sup>112</sup> as well as others, showed that the spleen serves as a filter for the red cells, and a trap. Sequestered there under conditions of hemoconcentration that remove them from the glucose that is readily available in circulating plasma, these cells, with their increased need for glucose, ultimately break down.

The exact nature of the membrane defect, however, still is obscure. Attention now is being directed to the membrane proteins.<sup>60,104</sup> Study of these proteins has been hampered by a lack of techniques for obtaining them in undenatured form. On the basis of *in vitro* studies it has been reported that there is abnormal aggregation of HS mem-

brane components and that microfilament formation is defective.<sup>60</sup> It has been postulated that membrane proteins of HS cells are genetically altered in such a way as to interfere with their proper conformation, perhaps into fibrils. Possibly as a result of mutations in the microfilamentous proteins of the red cell membrane, the normal plasticity of the red corpuscle is impaired.<sup>58</sup> The membrane protein abnormality may be associated with thiol groups in the membrane, according to electrophoretic studies.<sup>46</sup>

Spherocytosis and neonatal jaundice are found in the deer mouse,<sup>1</sup> but this animal model so far has not been found useful in studying the pathogenesis of HS in man.

## Hereditary Elliptocytosis (HE)

The circulating red cells of nonmammalian vertebrates are oval or elliptical and nucleated. Among the mammals, only camels and llamas have red corpuscles that are oval or elliptical in shape, but their corpuscles are not nucleated. In man, only a small proportion (1 to 15%)<sup>131</sup> of the red corpuscles are oval, but in persons with anemia the number of such cells may increase, especially in those with macrocytic, and, to a smaller extent, in those with microcytic anemias.<sup>131</sup> Oval macrocytes are typical of the megaloblastic anemias (Chapter 14) and oval and elliptical cells are seen in sickle cell anemia, thalassemia, and in hemolytic anemias associated with red cell enzymatic defects. The varieties of oval and elliptical shapes that may be encountered are illustrated in Figure 21-5.

Fig. 21-5 Camera lucida drawings of erythrocytes found in the blood of persons having the elliptical red corpuscle trait. *a* represents an approximately normal cell, *b*, *c*, and *d* represent "oval" forms, *e*, *f*, *g*, and *h* represent "rod" forms. (From Florman and Wintrobe,<sup>131</sup> courtesy of the authors and Bulletin of the Johns Hopkins Hospital)

In patients with the inherited disorder HE, at least more than 25%<sup>122</sup> and usually as many as 50 to 90%<sup>143</sup> of the red cells are rod-shaped or oval (Fig. 21-6).

### Incidence and Genetics

The incidence of HE in the general population is about 0.04%.<sup>122, 161</sup> This anomaly, first noted by Austin Flint<sup>130</sup> and described by Dresbach in 1904,<sup>129</sup> is widespread throughout the world<sup>125, 132, 136, 139, 152, 156</sup> and is transmitted as an autosomal dominant trait.<sup>126, 133, 135</sup> Members of either sex may be affected (Fig. 21-7). Linkage of the gene for elliptocytosis with the Rh blood type has been demonstrated in some families<sup>134, 145</sup> but not in others,<sup>122, 126, 133, 145</sup> and it was suggested that the linked form of elliptocytosis is less likely than the nonlinked variety to be associated with hemolytic anemia.<sup>122, 161</sup> It is difficult to draw a sharp distinction on this basis, however. Data are conflicting regarding the uniformity of hemolytic manifestations in family members,<sup>125, 149, 161</sup> in part perhaps because clear differentiation between compensated hemolytic disease and freedom from hemolysis has not always been made.

HE has been observed in association with G6PD deficiency,<sup>148, 152</sup> glyoxalase II deficiency,<sup>157</sup> thalassemia,<sup>120</sup> HbS, HbC,<sup>160</sup> and hereditary hemorrhagic telangiectasia.<sup>150</sup>

Fig 21-6 Hereditary elliptocytosis (Blood smear, Wright stain  $\times 900$ )

### Clinical Manifestations

In the majority of persons carrying this trait, no clinical manifestations are present; in about 12%, evidence of increased hemolysis is found, according to one estimate.<sup>150</sup> In one family, however, 57% manifested signs of hemolysis at one time or another.<sup>139</sup> Anemia may or may not be noted even when hemolytic disease is present, this being governed by the capacity of the bone marrow to compensate for the accelerated destruction. In some instances the erythrocyte count may be higher than normal, although the amount of hemoglobin and the volume of packed red cells are normal.<sup>131</sup> The hemolytic disorder may be accompanied by signs of chronic hemolysis (Chapter 20) such as reticulocytosis, splenomegaly,<sup>159</sup> leg ulcers,<sup>138</sup> and, occasionally, even skeletal abnormalities.<sup>123</sup> Anemic crises have been observed, possibly related to infections.<sup>128</sup>

### The Blood Picture

Unlike sickle cells, elliptocytes do not change their shape in sealed fresh blood preparations.<sup>131, 145</sup> On the average they are 8.1  $\mu\text{m}$  long and 5.3  $\mu\text{m}$  wide,<sup>131</sup> but they may be as long as 12.2  $\mu\text{m}$  and as narrow as 1.6  $\mu\text{m}$ . Their axial ratio was stated to be 0.78.<sup>143</sup> In one study, MCV ranged from 50 to 76 fl and the MCH 18 to 28 pg with MCHC within normal limits,<sup>131</sup> but others have reported normal values for MCV and MCH.<sup>127, 150</sup>

The number of elliptical forms in the blood of a newborn child gradually increases until the child is three or four months of age, after which their number stabilizes.<sup>136, 137, 138</sup> Hemolysis and hyperbilirubinemia requiring exchange transfusion have been observed in the newborn period; at this time the morphologic picture may more closely resemble pyknocytosis (page 765) than elliptocytosis.<sup>121</sup>

The life span of elliptocytes may be normal or, in hemolytic disease, it is shortened.<sup>146</sup> No morphologic differences have been detected between elliptocytes with normal or shortened life span.

Fig 21-7. Family K (Negro), showing incidence of elliptical cell trait. The open blocks represent subjects in whom many elliptical cells were found. The proportion of such cells is given within the block. A hatched circle represents an individual whose red corpuscles were not elliptical, an open circle indicates those not examined, and a black circle refers to those dead. Each individual's age is shown in parentheses below the initials. (From Florman and Wintrobe,<sup>131</sup> courtesy of the authors and Bulletin of the Johns Hopkins Hospital.)

Osmotic fragility, even after incubation, and autohemolysis usually are normal,<sup>113,135,141,150</sup> but when there is hemolytic activity they have been found to be abnormal.<sup>126,128,135,158</sup> When autohemolysis was increased it was reduced by the addition of glucose or ATP.<sup>135,158</sup> In persons with hemolytic disease, reticulocytes are increased, frequently to levels up to 10%, occasionally higher, and spherocytes may be present. Haptoglobin is decreased.<sup>133,139</sup> Spherocytes may increase in number post-splenectomy, but the number of reticulocytes decreases to normal values.

The reaction to Coombs' test is negative in uncomplicated cases.

## Diagnosis

As mentioned previously, elliptocytes may be present in many forms of anemia but not in the numbers characteristic of HE. Persons harboring this anomaly, however, may develop iron deficiency or other forms of anemia and, as has been noted, this hereditary trait may be associated with other inherited abnormalities. These must be differentiated by the usual methods. Differentiation from HS may not be easy. The diagnosis of HE

is based on the large proportion of elliptocytes present in the blood (page 760).

## Treatment

Sequestration of the red cells in the spleen has been observed<sup>126</sup> and splenectomy has been found to relieve the hemolytic anemia,<sup>124,142,143,146</sup> even though the morphologic abnormality of the red corpuscles is not altered.<sup>143</sup> In fact, the microovalocytes, bizarre-shaped red cells, and red cell fragments that may be found in the blood of patients with hemolysis may increase in number following splenectomy.<sup>159</sup>

## Pathologic Physiology

The factors that determine the anomalous shape are unknown. The nucleated precursors of elliptocytes are round,<sup>131</sup> and even reticulocytes do not show the degree of elliptocytosis seen in mature corpuscles.<sup>155</sup> The erythroblasts with elliptical nuclei, described by Löffler and Hansen,<sup>144</sup> probably represent a different anomaly. The elliptical shape persists in various isotonic solutions, in surviving cells (ghosts) in hypotonic saline solution, and in the plasma of normal individuals.<sup>155</sup>

Radioautographs showed the membrane cholesterol to be concentrated toward the convex surface around the periphery of the cells, i.e., the point of greatest convexity.<sup>147</sup> Electron microscopy and shadow-casting showed the hemoglobin to be aggregated in a bipolar arrangement.<sup>153</sup> No abnormalities in the hemoglobin and no deficiency in glycolytic enzymes have been discovered.<sup>126, 142, 143, 156</sup>

On sterile incubation *in vitro*, a more rapid than normal decline in cellular ATP and 2,3 DPG was reported<sup>135</sup> and a 40% increase in the sodium efflux that is inhibited by ouabain was observed.<sup>154</sup> These findings suggest a membrane permeability defect similar to that of HS, but neither the degree of ATP instability nor the rate of sodium efflux has been found to be correlated with the presence or absence of shortened red cell survival.

No feature that clearly differentiates the asymptomatic<sup>161</sup> and the hemolytic states of HE has been identified. Although persons with the type of elliptocytosis that is linked with the Rh blood group have usually been free of hemolytic disease, this has not always been the case.<sup>126, 142</sup> Neither has the same degree of hemolytic activity been demonstrated in members of the same family. Homozygosity for the trait was suggested as the cause of severe hemolysis in certain patients.<sup>143, 152, 161</sup>

## Acanthocytosis

An acanthocyte is a spherical red corpuscle with several irregularly spaced, large ("thorny") projections that vary in width and length. As discussed in Chapter 13 (page 541) its appearance contrasts with that of another form of spicule cell, the echinocyte or burr cell that possesses regularly spaced spicules, more uniform in size and more numerous than the projections of acanthocytes.<sup>183</sup>

### Abetalipoproteinemia

#### Clinical Manifestations

First recognized in a girl born of parents who were first cousins,<sup>170</sup> abetalipoproteinemia

is characterized by retarded growth; steatorrhea; progressive ataxic neurologic disease involving the posterior columns, the pyramidal tracts, and the cerebellar pathways; and retinitis pigmentosa.<sup>189, 200</sup> The blood contains numerous acanthocytes (Fig. 21-8), but, despite these striking morphologic abnormalities, anemia is absent or mild.<sup>189</sup> The serum lipids are extremely low, causing the serum to appear remarkably transparent. The serum contains no  $\beta$ -lipoprotein (low-density lipoprotein) and the serum cholesterol, triglyceride, and phospholipid levels are lower than normal.<sup>191, 194, 195</sup> The cholesterol content of acanthocytes is either normal<sup>191</sup> or high, but lecithins, the major class of phospholipids in normal human red cells, are decreased,<sup>172, 189, 192</sup> both in relative and absolute amounts, and sphingomyelins are increased.<sup>204</sup> Observed in a number of other instances in the offspring of consanguineous marriages,<sup>170, 175, 189</sup> the syndrome is rare and is thought to be inherited from both parents as an autosomal recessive trait.

Younger red cells in persons with this disorder show minimal or no morphologic distortion, but the degree of cell deformity increases with cell maturation or aging, or both.<sup>192</sup> During 48 hours' incubation the red cells become permeable to hemoglobin more rapidly than do normal cells.<sup>197</sup> This auto-hemolytic pattern is accentuated if the blood is collected in EDTA and maintained at room temperature for 48 to 72 hours. It is inhibited

Fig 21-8. Acanthocytes from a patient with abetalipoproteinemia (Courtesy of Dr Robert S Lees)

by conditions leading to better preservation of intracellular ATP.<sup>197</sup> Small amounts of whole serum, separated low- and high-density lipoproteins, and certain emulsions of plasma lipids inhibit the autohemolysis of acanthocytes.<sup>203</sup> Peroxidative stress increases hemolysis, and substances that prevent lipid peroxidation, such as tocopherol (Chapter 4, page 148), prevent hemolysis.<sup>174,184</sup> Osmotic fragility usually is in the normal range.<sup>197</sup> The *in vivo* life span of the red cells in abetalipoproteinemia may be slightly shortened,<sup>197,204</sup> but this accelerated destruction is intermittent. Slightly increased or normal numbers of reticulocytes are observed.<sup>197</sup>

### Biochemical Defect

The primary biochemical lesion in abetalipoproteinemia may be a selective one, affecting the main apolipoprotein ( $\beta$ -apoprotein, apoLP-ser) of low-density lipoprotein.<sup>179</sup> The  $\beta$ -apoprotein seems to be an obligatory component of chylomicrons as well as very low-density lipoprotein. Thus, the formation of these lipoproteins also is defective and transportation of long-chain fatty acids from the gut or mobilization of triglyceride from the liver cannot take place in normal fashion.<sup>182,185</sup> In contrast to celiac disease, fat absorption alone is impaired and the absorption of other nutrients such as vitamin B<sub>12</sub> is normal,<sup>197</sup> as is cation permeability.<sup>180</sup> Deficiencies of the fat-soluble vitamins A, E, and K may be responsible for at least some of the clinical features of abetalipoproteinemia, but their precise role in the pathogenesis of the retinal and neurologic changes remains to be defined. The morphologic features of the acanthocytes can be reversed *in vitro* by non-ionic detergents,<sup>201</sup> an observation indicating the importance of the plasma lipid and lipoprotein milieu to normal red cell structure and function.

The activity of the serum cholesterol esterifying enzyme, lecithin:cholesterol acyltransferase (LCAT), has been found to be reduced to approximately 40% of normal in persons with abetalipoproteinemia,<sup>172</sup> as well as in most patients with liver disease who

have either target cells or spur cells.<sup>171</sup> This implies that the enzyme plays an important role in the metabolism of unesterified cholesterol and lecithin in serum lipoproteins, but its role in the pathogenesis of abetalipoproteinemia still is uncertain.

A number of patients have been reported in whom variant syndromes have been noted.<sup>178,186</sup> These included patients who were affected with acanthocytosis and progressive neurologic impairment and yet normal lipoproteins were found. In others, diminished but detectable beta-lipoproteins were present.

### Diagnosis

Abetalipoproteinemia is suspected on the basis of clinical findings, acanthocytosis, and markedly diminished serum cholesterol and triglyceride concentrations. The diagnosis is confirmed by absence of beta-lipoprotein in plasma and the characteristic morphologic appearance of a small intestinal biopsy specimen; the mucosal cells are filled with lipid droplets, especially at their villous tips. Fat droplets are virtually absent in the intercellular space and lacteals.

Abetalipoproteinemia should not be confused with familial alpha- (high-density) lipoprotein deficiency (Tangier disease), in which hypocholesterolemia (cholesterol concentration <100 mg/dl) usually also occurs and enlargement of the spleen, liver, and lymph nodes may be present but acanthocytosis is not noted.<sup>177</sup> In alpha-lipoprotein deficiency, increased proportions of phosphatidyl choline and decreased proportions of sphingomyelin in both the plasma and the red corpuscles have been reported.<sup>196</sup>

As discussed in Chapter 19 (page 706), patients with hepatocellular disease may have hemolytic anemia associated with a high proportion of cells resembling the acanthocytes of abetalipoproteinemia ("spur cells").<sup>171</sup> This is attributable to the markedly increased cholesterol content and cholesterol-phospholipid ratio of the cells. The various forms of spicule distortion of red cells are discussed in Chapter 13.

## Treatment and Prognosis

Although there is no definitive therapy for patients with abetalipoproteinemia, and some of the patients have succumbed at an early age, treatment with high doses of vitamins A and E has been given in the hope that the abnormalities in retinal and neurologic function will be ameliorated.

## Other Disorders Involving the Red Cell Membrane

### Stomatocytosis

✓ A linear area of central pallor in red corpuscles as seen in stained films characterizes the "stomatocyte." The slit-like appearance contrasts with the normal circular area of central pallor of red cells. Stomatocytes seem to be uniconcave, and in wet preparations they have a bowl-like appearance. They can be seen occasionally in blood films and occur as a transient phenomenon in persons with acute alcoholism, but in several reported patients with inherited disease they were present consistently, in large numbers, and in association with mild or severe hemolytic anemia (see Fig. 13-2, page 545).

The mother and daughter reported by Lock and his associates<sup>215</sup> manifested symptoms resembling HS, in that they had hemolytic anemia of moderate degree, associated with greatly increased osmotic fragility. Their disease differed from HS in that stomatocytes rather than spherocytes were found in the blood and splenectomy was of no benefit. The survival of their red cells was very short, even after splenectomy, and was even shorter when their cells were transfused into normal recipients with intact spleens. Similar cases have been reported by others.<sup>217,219</sup> Differing somewhat from these cases are those in a 6 month old child<sup>226</sup> and in a father, son, and grandson of one family.<sup>221</sup> These patients had a mild hemolytic disorder characterized by stomatocytes that contained very high levels of sodium and low levels of potassium. The red cells were found

to be 20 to 40 times more permeable to  $\text{Na}^+$  and  $\text{K}^+$  than normal. There was no evidence of abnormality in the parents of the 6 month old child, but in the family studied by Oski and his associates<sup>221</sup> the pattern of inheritance resembled that of HS and in these patients, as in those with HS, osmotic fragility was increased and splenectomy was beneficial. It was observed that as the red cells aged they became more permeable to  $\text{Na}^+$ . The observations in these cases suggested an abnormality in the functioning of the red cell cation pump.

From Australia, mild hemolytic anemia with stomatocytosis and normal osmotic fragility has been reported in some Mediterranean migrants,<sup>211,213</sup> but, in others, stomatocytosis was present in the absence of anemia or reticulocytosis.<sup>220</sup> In none of the subjects of Mediterranean origin were abnormalities of red cell metabolism or of hemoglobin found<sup>211</sup> nor was there evidence of electrolyte changes<sup>213</sup> or abnormal osmotic fragility.<sup>211</sup>

Still another form of hereditary hemolytic anemia associated with stomatocytosis has been described in members of a Swiss-German family.<sup>218</sup> In these subjects, osmotic fragility was decreased, and red cell  $\text{Na}^+$  content,  $\text{K}^+$  leak, and sodium pump rates were increased. Autohemolysis was type I. The parents of these patients were consanguineous and inheritance was autosomal dominant.

In still another family, elliptically shaped erythrocytes with one or more transverse slitlike areas of decreased density and with increased permeability to  $\text{Na}^+$  and  $\text{K}^+$  were associated with no anemia or evidence of hemolytic disease.<sup>212</sup> In vitro erythrocyte glucose consumption was 60% greater than that of normal controls. Thus it appears that erythrocytes can compensate for increased cation permeability without any ill effects being apparent.

### Hereditary Nonspherocytic Hemolytic Anemia with Altered Erythrocyte Phospholipid Composition

In a family from the Dominican Republic a dominantly transmitted mild hemolytic

anemia was observed in which osmotic fragility was decreased while autohemolysis was slightly increased but was corrected to nearly normal by the addition of glucose. However, unique morphologic characteristics were not observed.<sup>214</sup> The life span of isologous, but not homologous, transfused erythrocytes was reduced. An absolute increase in phosphatidyl choline (lecithin) (PC) in the red cells was demonstrated, but there was no detectable abnormality of plasma lipids. The accumulation of PC in these patients' cells has been shown to be due to inhibition of the transfer of actively acquired esterified membrane fatty acid from PC to phosphatidylethanolamine (PE) prior to its return to the plasma<sup>223,225</sup> (see Chapter 3, page 97). This is associated with increased cation permeability and with increased glycolysis because of the higher energy requirement for operation of the cation pump<sup>224,225</sup>; it results in increased vulnerability of the red cells to stress.

### LCAT Deficiency

Total absence of lecithin:cholesterol acyltransferase associated with normocytic anemia and attributed to slight hemolysis and reduced compensatory increase in erythropoiesis has been described in three sisters.<sup>178</sup> The erythrocyte content of cholesterol was markedly increased and PE and sphingomyelin were decreased. In contrast to hereditary acanthocytosis, in which LCAT is reduced but not absent (page 763), numerous target cells were seen in the blood smear.

### "Infantile Pyknocytosis"

"Infantile pyknocytosis" refers to the condition in which distorted, burr-like red corpuscles, probably caused by extracorporeal factors,<sup>210</sup> are found in association with a clinical picture consistent with that of erythroblastosis fetalis in some instances, and that of anemia and jaundice developing in the first few weeks of life in others. No cause has been discovered and the usual management of neonatal hemolytic disease has been successful in this disorder.

## *Hereditary Hemolytic Anemias Associated Mainly with Abnormalities in the Glycolytic Metabolic Pathway of Erythrocytes<sup>60,91</sup>*

### **Pyruvate Kinase Deficiency Other Enzyme Deficiencies**

**F**OLLOWING the recognition of hereditary spherocytosis (HS) (Chapter 21) as a specific entity it came to be appreciated<sup>28</sup> that cases of congenital hemolytic anemia which do not conform to this classic pattern are sometimes encountered. As described elsewhere (Chapter 20), under the term "congenital nonspherocytic hemolytic anemia," a number of investigators drew attention to the fact that in certain of these subjects spherocytosis and increased osmotic fragility of fresh blood are not found, hemoglobin abnormality cannot be demonstrated, and splenectomy is only partially beneficial, if at all.<sup>19</sup> The autohemolysis test (page 735) of Selwyn and Dacie<sup>57</sup> served additionally to distinguish these cases, categorizing two types; furthermore, by revealing that the addition of glucose to the incubation mixture failed to prevent autohemolysis, in contrast to the effect in HS, the possibility arose that impaired glycolysis might be responsible for some of the observed differences.<sup>33,53,90</sup> The discovery of

glucose-6-phosphate dehydrogenase deficiency (Chapter 23) and the subsequent demonstration of red cell pyruvate kinase deficiency in association with hereditary nonspherocytic hemolytic anemia<sup>63</sup> initiated a series of studies that have since revealed a number of other hereditary enzymatic deficiencies in erythrocytes, most of which are associated with various degrees of hemolytic anemia. Those involving the glycolytic pathway will be discussed here. Those related to the hexose monophosphate shunt and glutathione metabolism, especially glucose-6-phosphate dehydrogenase deficiency, will be considered in Chapter 23.

### **Pyruvate Kinase (PK) Deficiency**

Of the enzymatic deficiencies involving the Embden-Meyerhof pathway, PK deficiency is the most common and can serve as the prototype for the remainder, which are quite rare. A review published in 1971 listed 135 well-documented cases, including some previously described as instances of Dacie's Type II nonspherocytic hemolytic anemia.<sup>60</sup> Members of both sexes are equally affected. Al-

Table 22-1. Some Features of Certain Inherited Red Blood Cell Enzyme Deficiency Disorders

Enzyme Deficiency* <sup>1, 114</sup>	Mode of Inheritance	Severity of Anemia	Hemolysis after 24 to 48 Hr Incubation at 37°C			ATP	Autohemolysis Type	WBC Enzyme Concentration	Associated Disorders
			no additive	glucose					
Glycolytic pathway									
HK <sup>15, 16, 117</sup>	AR	Mild to severe	++ or +++	+		+	I	N A?	Probably none
GP1 <sup>15, 16, 18, 105</sup>	AR	Moderate to severe	++ or +++	+		+	I	Low, also low in plasma	None
PFK <sup>11, 12, 120</sup>	AR?	Mild	+++					N (low in muscle)	Myopathy
TP1 <sup>16</sup>	AR	Severe	++	0		0	As in HS	Low (also low in muscle, serum CSF)	Neurologic myocardial infectious
2,3 DPGM <sup>11, 16, 107</sup>	AR	Severe to moderate	+++	+		+	I		None
PGK <sup>11, 116</sup>	X-linked	Severe to moderate	++	0		+	I	Low	Mental retardation
PK <sup>16</sup>	AR	Mild to severe	+++	+++		+	II	N	None

Glutathione metabolism									
G6PD (Chapter 23)	X-linked	None to severe	++ or +++	+		+	I	N A	Sensitivity to oxidant drugs, etc
6PGD (Chapter 23)	AR	None	+++	+		+	I		
GR (Chapter 23)	AD?	?	+++	++		0	II	N	
GSH-Px (Chapter 23)	AR	Mild to moderate?							Drug sensitivity?
Glutathyl cysteine synthetase	AR	Mild	+	+					
GSH synthetase	AR	Mild							
Other RBC enzymes									
AK <sup>110</sup>	AR	Moderate?							
RPK <sup>111</sup>	AR?	Moderate	+++	++		0	II		
ATPase <sup>117, 10</sup>	AD	Moderate							

The abbreviations for the various enzymes are explained in the text

AR means autosomal recessive AD autosomal dominant; N means normal, A abnormal; HS is hereditary spherocytosis. References are given in the first column, except for enzymes involved in glutathione metabolism, which will be found in Chapter 23.

though most of the cases have been found in persons of Northern European origin,<sup>8</sup> the disorder has been described in several Italians,<sup>14</sup> in a Syrian, a Spanish infant, a Mexican child, in American Negroes, in Japanese,<sup>37</sup> and in Chinese.<sup>60</sup> A high frequency was identified in an inbred Amish commune<sup>12</sup> and in Chinese newborn.<sup>22</sup> As additional cases are reported it is becoming apparent that PK deficiency is a somewhat polymorphous disorder.

### Clinical Manifestations

The characteristic features of chronic hemolytic anemias, outlined in Chapter 20, are present: anemia of varying degree, jaundice, splenomegaly, episodes of dark urine, increased incidence of gallstones.<sup>60</sup> The hemolytic process may be severe<sup>11,40</sup> and may be aggravated by intercurrent infection or other stressful situations.<sup>32,33,49,63</sup> Aplastic crises have been observed.<sup>32,44</sup> Remarkable is the variation in the severity of the disease,<sup>60,63,67</sup> ranging from pronounced neonatal jaundice requiring exchange or multiple transfusions<sup>8,22</sup> to a fully compensated hemolytic process in adults.<sup>44,63</sup> PK deficiency generally is a more serious disease than HS for two reasons, i.e., the greater degree of clinical severity in many PK-deficient subjects and the absence of unequivocal benefit from splenectomy.

In most of the patients with PK deficiency, anemia or jaundice have been noted in infancy or early childhood but in some the disease has not been detected until adulthood, even not until late in life.<sup>41</sup> Although survival to adult life is common, in the severe form found in Amish kindreds, death before the age of 3 or 4 years was likely unless splenectomy was performed.<sup>11,12</sup>

General development usually is normal, but may be impaired, and bone changes associated with hyperplastic bone marrow, such as those seen in other hereditary chronic hemolytic anemias (Chapters 25, 26), may result in prominence of the frontal cranial eminences.<sup>1,11,63</sup> Splenomegaly is slight to moderate in degree. Chronic leg ulcers are

rare.<sup>60,63</sup> Pregnancy has been tolerated without unusual complications.<sup>33,37</sup>

### Laboratory Findings

#### *The Blood*

Although the degree of anemia varies widely, hemoglobin levels of 6 to 12 g/dl and packed cell volumes of 0.17 to 0.37 l/l have been most common.<sup>60</sup> A moderate degree of spontaneous fluctuation may be observed. Extremely low levels have been reported during the first few years of life with stabilization at higher levels later.

Macrocytosis of slight to moderate degree is noted in association with reticulocytosis. The percentage of reticulocytes ranges from 2.5 to 15.0, but values as high as 56.0% have been reported after splenectomy.<sup>60</sup> There is moderate polychromatophilia, as well as variable numbers of nucleated red cells. Although only slight aniso- or poikilocytosis are usually present, occasional, irregularly contracted erythrocytes with irregular borders ("spicules"<sup>41</sup>), tailed poikilocytes, or elongated forms have been described,<sup>33,37</sup> and, in infants and young children, cells resembling acanthocytes have been reported.<sup>49</sup> The leukocyte and platelet counts are normal or slightly increased.

*Osmotic fragility* of fresh red cells is normal, but on incubation different degrees of increased fragility are found.<sup>11,37,44,63</sup> In the autohemolysis test, increased hemolysis usually is observed after 48 hours of sterile incubation and this is not reduced by glucose but is correctible by ATP (Type II)<sup>23,24,63</sup>; however, in mildly affected individuals this test may give normal findings and a few instances of Type I autohemolysis were reported.<sup>2,15,37,60</sup>

#### *Other Laboratory Findings*

Serum bilirubin is moderately elevated, plasma hemoglobin is not increased, but serum haptoglobin may be decreased or absent.<sup>11,44,48</sup> Fecal urobilinogen is increased. Serum iron is normal or slightly increased

and total iron-binding capacity is normal. Reactions to the Coombs' test are negative and Hb F and Hb A<sub>2</sub> concentrations are normal.

Ferrokinetic studies indicate active effective erythropoiesis and there is moderate to severe shortening of the life span of the red cells (Fig. 20-2),<sup>42</sup> although this is quite variable.<sup>60</sup> The significance of <sup>51</sup>Cr half-time measurements in this disorder may well be questioned since the cells available for tagging are presumably those that have survived the early rapid attrition of the most severely affected erythrocytes.<sup>60</sup> As in other hemolytic disorders, erythroid hyperplasia is found in the bone marrow.

### Pathologic Physiology

Erythrocyte pyruvate kinase is an enzyme that may have a molecular weight of 225,400.<sup>17</sup> It catalyzes the regeneration of ATP from ADP and provides the pyruvate for the subsequent conversion to lactate, as follows: phosphoenolpyruvate + ADP  $\xrightarrow{\text{PK}}$  pyruvate + ATP. The precise pathogenetic mechanism resulting in the ultimate destruction of PK-deficient cells and the consequent hemolytic anemia still is obscure. There is no close correlation between the enzyme level and the apparent severity of the hemolytic anemia.<sup>23</sup> Various possibilities have received attention.

It is from ATP that erythrocytes derive their energy for vital functions such as maintenance of cationic gradients. Consequently, it is reasonable to assume that the impairment in ATP regeneration in PK deficiency accounts for their diminished life span.<sup>40</sup> Rather than gaining sodium, as occurs in HS (Chapter 21), PK-deficient erythrocytes lose potassium.<sup>33,42</sup> This probably explains the corpuscular distortions that have been described in the blood and even makes the cells vulnerable to destruction in the liver, as well as the spleen.

Several observers have noted increased concentration of reticulocytes in the spleen of patients with PK deficiency.<sup>11,40,42</sup> Theo-

retically, reticulocytes should be less vulnerable than mature erythrocytes to deficient PK activity since they possess mitochondria and can utilize mitochondrial oxidative phosphorylation to maintain ATP levels.<sup>33</sup> However, PK-deficient reticulocytes with particularly low levels of PK activity are especially reliant upon oxidative phosphorylation in the mitochondria. In the spleen such cells may be subjected to metabolic factors, such as low pH, low P<sub>O<sub>2</sub></sub>, and low glucose level, that may handicap reticulocyte mitochondrial metabolism.<sup>36</sup> With the consequent rapid fall of ATP level, selective sequestration of the defective reticulocytes would occur. Various phases of reticulocyte phagocytosis by the cordal macrophages of the spleen have been observed.<sup>35</sup> Some variation in the degree of impairment of PK activity in erythrocytes, whether they be reticulated or mature, has been postulated.

Whether PK deficiency is the primary defect in this disorder or is only indicative of another abnormality, either of the red cell membrane or of its metabolic processes,<sup>61</sup> is unknown. Abnormal accumulations of glycolytic intermediates have been found in the red corpuscles, especially 2,3 DPG<sup>23</sup> and phosphoenolpyruvate,<sup>31</sup> but these can be explained by the fact that the metabolic defect is late in the glycolytic pathway and such accumulations might be expected (Fig. 3-14, page 103).

### Genetics

Although rare exceptions have been reported,<sup>30</sup> it is generally accepted that erythrocyte PK deficiency is inherited as an autosomal recessive trait. Only the red cells are affected. Leukocytes, for example, are not affected.<sup>63</sup> Only individuals homozygous for this defect manifest clinical disease.<sup>60,63</sup> In homozygotes, erythrocyte PK activity has been found to be in the range of 5 to 25% of normal mean values; erythrocytes of heterozygotes generally have about half normal PK activity. The PK of human red cells is known to exist normally in at least three isozymic forms.<sup>6</sup> As with other enzymes, there are mutant forms of PK<sup>7,31,53</sup> which,

though capable of catalyzing the same biochemical reactions, have abnormal kinetic properties that result in impaired catalytic efficiency at the low substrate concentrations found in erythrocytes.<sup>9</sup>

The observations of a number of investigators indicate that PK deficiency is genetically heterogeneous.<sup>47,51</sup> Extreme intrafamilial differences between PK phenotypes have been observed.<sup>67</sup> Double heterozygosity for mutant PK isozymes and deficient normal enzyme probably explain seeming normality in one or the other of the parents of affected individuals.<sup>13,52,53,60</sup> This would account for at least some of the hypotheses, proposing autosomal dominant inheritance of PK deficiency, that were based on failure to demonstrate quantitative deficiency of normal PK.<sup>2,15,66</sup>

## Diagnosis

The diagnosis depends first on recognition by the usual criteria (Chapter 20) of the fact that one is dealing with a hereditary hemolytic anemia of chronic nature that differs from HS, eg, absence of spherocytosis, normal osmotic fragility of fresh blood, and a type II autohemolysis pattern (page 735). A history may be obtained of severe jaundice and even exchange transfusion in the neonatal period without evidence of fetomaternal Rh or ABO incompatibility. The history, however, may not necessarily reveal the hereditary nature of the disorder or even chronicity and, consequently, the possibility of acquired hemolytic processes must be excluded by history and negative reactions to the Coombs' test and to tests for paroxysmal nocturnal hemoglobinuria (Chapter 29). In a simple screening test for PK activity,<sup>5</sup> the PK reaction is coupled to the NADH-dependent conversion of pyruvate to lactate. Since NADH fluoresces when irradiated with long-wave ultraviolet light and NAD does not, the reaction can be monitored visually. Phosphoenolpyruvate, NADH, and LDH are added to blood, which supplies PK. As pyruvate is generated, NADH is utilized. In PK deficiency the NADH fluorescence persists

even for 45 to 60 minutes, in contrast to the disappearance of fluorescence within 15 minutes when normal blood is used. False results can be expected, however, if the patient has been transfused recently.

Whenever possible, an abnormal result should be confirmed by quantitative assays.<sup>59</sup> Studies of the kinetics, stability, and other properties of the enzyme may be required in order to recognize kinetically aberrant and mutant isozymes. Since the ratio of the PK activity of leukocytes to erythrocytes is 300:1, efficient separation of these cells before measurements are made is essential.<sup>69</sup> Normally values for males and females are similar, but the normal range for red cell PK activity is quite wide and the lower limits of normal have been difficult to define.<sup>60</sup> PK activity is increased in cord blood and in reticulocytes. Subnormal PK values have been observed only in the acute leukemias<sup>9,38,60</sup> and possibly also in refractory or sideroblastic anemia.<sup>9</sup>

## Treatment

There is no specific therapy. The usual hematopoietic agents and steroids are not effective. The anemia may sometimes be of sufficient severity to require blood transfusion, but this procedure is best avoided, if possible, not only because of the immediate hazards of transfusion but also because of the long-term possibilities of iron overload. Improvement has been observed following splenectomy, especially in infants and young children with severe disease.<sup>32,33,42,45,49,60</sup> This can be explained by the exceptional vulnerability of some reticulocytes to splenic sequestration,<sup>36,42</sup> discussed earlier. In the severest forms of PK deficiency, splenectomy seems to have been necessary to permit survival.<sup>11</sup> In some instances, as an affected child grew older, anemia diminished in severity sufficiently to decrease or eliminate the need for blood transfusion. Even osseous defects were found to regress.<sup>11</sup>

Splenectomy, however, is an imperfect form of therapy. An appreciable degree of hemolysis persists in all subjects, and hemo-

lytic<sup>33</sup> or aplastic<sup>32,41</sup> crises have occurred in splenectomized patients. After a period of improvement postsurgically, a gradual decrease in hemoglobin levels may take place.<sup>44</sup> The persistently impaired red cell survival can be attributed to continued, although slower, destruction in the liver.<sup>33,42</sup> Folic acid supplementation (2 to 5 mg daily, given by mouth) has been used in the hope of preventing complicating megaloblastic anemia.

In families afflicted with the disorder, newborns should be checked for kernicterus and exchange transfusion performed when necessary.

### Prognosis

As mentioned earlier, intercurrent infections and other stressful situations may be associated with exacerbations, hemolytic and aplastic crises may occur, and cholelithiasis may develop. Although the degree of severity of the disease varies greatly, survival into adulthood is common.

## Other Enzyme Deficiencies<sup>111</sup>

As mentioned previously, PK deficiency serves as a prototype for deficiencies of certain other enzymes that participate in the glycolytic metabolic pathway of the erythrocyte. In general, when associated with anemia the clinical manifestations of such defects are those of a hereditary nonspherocytic hemolytic anemia. They resemble PK deficiency in many respects, but there are two important exceptions to this generalization. First, in contrast to the autosomal mode of inheritance that characterizes PK deficiency and most of the other glycolytic defects, phosphoglycerate kinase (PGK) deficiency is X-linked. Second, although in a number of instances the enzyme deficiency affects only erythrocytes, or at least significant ill effects are related only to the erythrocyte deficiency, in glucose phosphate isomerase (GPI) deficiency leukocytes also are involved and in triosephosphate

isomerase (TPI) deficiency a great many tissues are affected, resulting in widespread clinical manifestations, especially in the nervous system.

In contrast to PK deficiency, type I auto-hemolysis<sup>57</sup> (moderate increase in hemolysis only partially prevented by the addition of glucose) has been described in hexokinase (HK) deficiency, GPI deficiency, and PGK deficiency. In TPI deficiency, both glucose and ATP protect against hemolysis, as in HS.<sup>114</sup> Specific assay methods are required if the deficiency is to be identified precisely. Such assays are available only in laboratories concerned with research in this field.<sup>9,60,114</sup>

In the following paragraphs the main features of these enzyme deficiency states will be presented, mainly in the order in which they participate in the glycolytic pathway (Fig. 22-1).

### Hexokinase (HK) Deficiency

This enzyme serves in the first step of the glycolytic sequence (Chapter 3). Normally, HK activity is considerably greater in reticulocytes than in mature cells, and this disparity between young and old cells is greater than is found in any of the other glycolytic enzymatic activities. However, in the five month old child with hemolytic anemia reported by Valentine et al,<sup>117</sup> even the HK activity of the patient's reticulocyte-rich blood was lower than that of normal blood. Her reticulocytes were "old before their time."<sup>117</sup> Splenectomy ameliorated the hemolytic process. Peculiarly, a male sibling who gave no evidence of hemolysis had red cell HK activity lower than the patient's, but this may have been explained by the fact that his cells were mainly mature rather than reticulocytes. Hemolytic syndromes also have been reported in two unrelated individuals,<sup>93</sup> as well as in a family in which the father and son exhibited an erythrocytic HK variant that, in this family, was demonstrated also in the leukocytes.<sup>104</sup> Splenectomy in the son was beneficial. In yet another family, panmyelopathy and multiple congenital anomalies of

Fig 22-1. Abbreviated diagram of pathway for the metabolic breakdown of glucose in the red corpuscle to show the position of the various enzymes (circled) that have been found deficient in the cases discussed. A more complete diagram is shown in Figure 3-14.

the Fanconi syndrome were associated with diminished HK activity,<sup>97</sup> but the significance of this family in relation to the above cases is obscure. The observed changes may have been the result of the marked chromosomal aberrations that were described.

### Glucose-Phosphate Isomerase (GPI) Deficiency

Since the first reported case of GPI deficiency,<sup>76</sup> a number of additional ones have been studied.<sup>79,103,105,114</sup> This deficiency is characterized by moderately severe hemolytic anemia, partially relieved by splenectomy.<sup>76,105</sup> Selective reticulocyte destruction in the spleen has been reported.<sup>98</sup> In a large proportion of cases the leukocytes shared the deficiency, but no evidence of dysfunction or of increased susceptibility to infection was found. Evidence of synthesis of a qualitatively changed subunit of the GPI molecule that is associated with faster inactivation of the enzyme *in vivo* was presented in one case.<sup>75</sup> Electrophoretic and kinetic studies indicate that GPI deficiency is heterogeneous,<sup>114</sup> and a number of enzyme variants have been noted.<sup>79,101</sup> A method for rapid detection of red cell GPI deficiency based on the appearance of fluorescence caused by TPNH has been described.<sup>78</sup>

### Phosphofructokinase (PFK) Deficiency

PFK deficiency has been reported to be associated with a severe myopathy (sometimes referred to as Type VII glycogen storage disease) together with nonspherocytic hemolytic disease.<sup>112</sup> Two cases have been reported in which the patients did not have muscle dysfunction.<sup>101,120</sup>

### Triosephosphate Isomerase (TPI) Deficiency

TPI deficiency involves not only erythrocytes but also leukocytes, spinal fluid, muscle and cultured skin fibroblasts, and perhaps all tissues.<sup>106,114</sup> Consequently, in addition to severe hemolytic anemia, severe and usually progressive neurologic disease is present and frequent infections and myocardial disease also may result. The gene governing TPI production may reside on the short arm of the number 5 human chromosome.<sup>109</sup> In a highly consanguineous kindred, TPI deficiency was associated with G6PD deficiency

and with the sickle cell trait in various combinations<sup>116</sup>

### 2,3 Diphosphoglyceromutase (2,3 DPGM) Deficiency

2,3 DPGM deficiency has been observed in presumed heterozygotes for this defect,<sup>81,86</sup> and one instance of severe hemolytic anemia in a child both of whose parents showed 50% of normal enzyme activity has been reported.<sup>107</sup> Since the product of the 2,3 DPGM reaction is 2,3 DPG, which plays such a significant role in oxygen affinity (Chapter 3), this type of deficiency is of unusual physiologic interest.

### Phosphoglycerate Kinase (PGK) Deficiency

PGK deficiency also is of special interest because, as in the PK reaction, PGK serves in an ATP regenerating step. In addition, like glucose-6-phosphate dehydrogenase (G6PD) deficiency (Chapter 23), PGK deficiency appears to be X-chromosome linked.<sup>118</sup> Hemolytic anemia associated with PGK deficiency in erythrocytes and leukocytes and with mild mental retardation was described in two male children of a large Chinese kindred and some of the female family members were mildly affected.<sup>118</sup> Similar findings were reported in a Japanese child, except that leukocyte enzyme determinations had not been carried out.<sup>102</sup> One instance of life-long hemolytic anemia in a female subject whose pedigree could not be studied also has been reported.<sup>94</sup>

### Lactic Dehydrogenase (LDH) Deficiency

Severe erythrocyte LDH deficiency without overt evidence of a hemolytic disorder has been reported in an individual who was homozygous for an autosomal, recessively transmitted, hereditary deficiency of a particular subunit (the H-subunit) of LDH.<sup>100</sup>

### Enolase and Aldolase Deficiencies

Chronic hemolytic anemia associated with erythrocyte *enolase* deficiency was reported in

two women who were sisters. In one of these subjects the condition was exacerbated by ingestion of nitrofurantoin.<sup>110</sup> Red cell *aldolase* deficiency has been described in a four year old child with chronic hemolytic anemia, hepatosplenomegaly, and mild mental retardation.<sup>77</sup>

### Deficiencies of Enzymes Not Functioning in the Glycolytic Cycle

In addition to those discussed in the chapter that follows (Chapter 23), in rare instances deficiencies of enzymes not functioning in the glycolytic cycle of the erythrocyte have been reported to be associated with hemolytic anemia. However, the relation of the enzyme deficiency to the anemia has not been clearly established. This comment applies to the reported cases of *adenylate kinase (AK)* deficiency,<sup>90</sup> one of which was associated with G6PD deficiency,<sup>111</sup> and also to *ribosephosphate pyrophosphokinase (RPK)* deficiency. In three unrelated kindreds,<sup>115,119</sup> chronic hemolytic anemia, moderate in degree, with reticulocytosis of about 10%, type II auto-hemolysis, and unusually prominent basophilic stippling of the red cells was associated with RPK deficiency. The levels of red cell glutathione and adenine nucleotides were increased. Although the deficiency was clearly hereditary in nature and was presumed to be transmitted as an autosomal recessive trait, a heterozygous carrier state could not be demonstrated in any of the family members. Whether the enzyme deficiency caused the hemolysis or represented an epiphenomenon was not firmly established.

In the subjects with RPK deficiency, ATP levels were increased. In two other inherited "*high ATP syndromes*," hemolysis was not present.<sup>82,121</sup> In a fourth variety,<sup>84</sup> however, chronic hemolytic anemia was present, but RPK measurements were not reported. In certain other cases, *low ATP* levels were observed in association with severe hemolytic anemia. These, however, were thought most likely to be related to increased catabolism of adenine nucleotides as a consequence of markedly increased utilization of ATP.<sup>99</sup>

## Adenosine Triphosphatase (ATPase) Deficiency

The stroma of the erythrocyte contains two types of ATPase, one of which requires  $\text{Na}^+$  and  $\text{K}^+$  for activation, is involved in ion transport, and can be completely inhibited by cardiac glycosides (page 100), whereas the other plays no role in ion transport and is insensitive to glycosides. Deficiency of the first type of ATPase has been described in a family, some of the members of which had nonspherocytic hemolytic anemia of moderate degree.<sup>60</sup> Dominant inheritance with incomplete penetrance was postulated. One additional case of a presumably similar disorder has been reported.<sup>87</sup>

## Glyceraldehyde-3-Phosphate Dehydrogenase (G3PD) Deficiency

The evidence regarding the association of hemolytic disease with G3PD deficiency and 2,3 DPG phosphatase deficiency is meager and unconvincing.<sup>114</sup>

### **Glutathione Peroxidase Deficiency**

### **Glutathione Deficiency**

## **G6PD Deficiency**

Glucose-6-phosphate dehydrogenase (G6PD) catalyses the initial step in the pentose phosphate pathway (PPP) (hexose monophosphate [HMP] oxidation pathway) of carbohydrate metabolism, causing reduc-

tion of NADP to NADPH. As discussed in Chapter 3 and illustrated in Figure 23-1, this enzyme plays a most important role in the red blood corpuscle because this corpuscle, having been deprived of an aerobic oxidative pathway by the loss of its mitochondria, depends on the PP oxidation pathway for the generation of NADPH. NADPH is required as a cofactor for red cell glutathione reductase to maintain glutathione (GSH) in the reduced state; reduced GSH, in turn, is necessary (1) for maintaining sulfhydryl groups within the red cell and perhaps in the red cell membrane, and (2), in conjunction with glutathione peroxidase, for the detoxification of peroxide.

The importance of G6PD for the normal metabolism and integrity of red blood corpuscles came to be recognized as the result of the investigation of the unique sensitivity of some individuals to the 8-aminoquinoline antimalarial compound, primaquine. As is outlined later in this chapter (page 785), this showed that the observed sensitivity was due to deficiency of the red cell enzyme G6PD. The original observations were made in

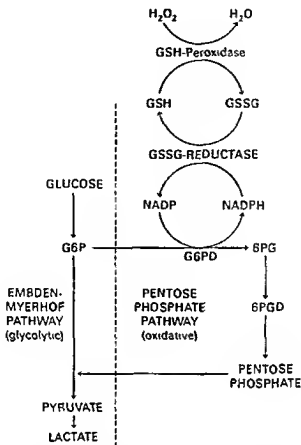

Fig 23-1 The role of G6PD in maintaining glutathione in the reduced state through the reduction of NADP to NADPH thereby making possible the reduction of oxidized glutathione (GSSG) and the role of GSH, in conjunction with GSH peroxidase in the detoxification of peroxide

American Negroes, but G6PD deficiency was later recognized in individuals of Mediterranean ancestry and ultimately in persons living in many parts of the world. Furthermore, it was noted that, whereas, in the subjects first studied, no clinical manifestations were present in the absence of exposure to a drug that caused oxidant stress, in other individuals a more severe degree of G6PD deficiency was present. For example, some subjects with hereditary nonspherocytic hemolytic anemia unrelated to drug ingestion were found to be deficient in G6PD, and still other clinical syndromes such as hemolytic anemia occurring during infection, favism, and neonatal jaundice also were found to be associated with G6PD deficiency. In addition, it is now clear that G6PD "deficiency" is not the con-

sequence of an absence or decreased amount of the enzyme, but is due to the presence of an abnormal, mutant enzyme with abnormal properties. Different variants, with different properties, appear to account for the observed clinical variability. By now, more than 80 such variants have been described. Thus the scientific investigation of sensitivity to an antimalarial compound led to the discovery and clarified the understanding of disorders which now are considered as probably affecting more than 100 million males throughout the world.

#### Genetics

The gene determining the structure of G6PD is carried on the X chromosome.<sup>23,52</sup>

Consequently, the defect is fully expressed in affected males. It cannot be transmitted from father to son, only from mother to son. Female heterozygotes for G6PD deficiency have two populations of cells—normal cells and G6PD-deficient cells. Although the average G6PD activity of a group of females heterozygous for G6PD deficiency is about half that found in normal males, the expression of the defect in individual female heterozygotes varies greatly<sup>48,89</sup> because X-inactivation appears to be a random process and may affect many more paternally derived X chromosomes than maternally derived ones, or vice versa.<sup>9</sup>

### Incidence and Geographic Distribution<sup>100</sup>

G6PD deficiency may be present in as many as 13% of American Negro males<sup>17,100</sup> and was found in 8.2% of Brazilian Negro males<sup>80</sup> and in 3% of Bantu males.<sup>24</sup> Perhaps 20% of the American Negro population are females heterozygous for G6PD deficiency.<sup>97</sup> In Sardinia, an incidence of 14.35% was recorded in contrast to a very low frequency (0.4%) in the Italian peninsula<sup>82</sup> and 2.7% in Malta.<sup>20</sup> In Northern European populations, the condition is even less common (0.1%). The deficiency has been found in most areas of Greece, but the highest frequencies, 9.5% and even higher, were in the lowland areas.<sup>91</sup> The condition is prevalent among Sephardic and Oriental Jews, and among Kurdish Jews 50% or more may be affected.<sup>100</sup> G6PD deficiency has also been observed in Arabs,<sup>54</sup> Southern Chinese,<sup>21,23,64</sup> and in Filipinos and Thais.<sup>100</sup> It seems to be rare in American Indians.<sup>58,96</sup> The high incidence among certain populations where malaria was once prevalent, as in the Greek lowlands,<sup>91</sup> like thalassemia (Chapter 26), has been attributed to the selective advantage the enzyme deficiency offers against malaria. It has been suggested that the malarial parasites, when harbored in G6PD-deficient red cells, either find that environment inadequate or are more likely to be destroyed in the RES together with their defective host.<sup>5,61</sup> The concept of "balanced polymorphism" is best supported, however, in relation to the geographic inci-

dence of the sickle cell trait and will be discussed in Chapter 25.

### The Enzyme and Its Variants<sup>107</sup>

Normal human G6PD consists of subunits, each having a molecular weight of about 50,000 to 55,000.<sup>51,104</sup> The subunit has pyroglutamic acid at the amino terminal and glycine at the carboxy terminal.<sup>104</sup> Depending on protein concentrations, pH, and the ionic strength of the solution, G6PD exists in various oligomeric forms—tetrameric when associated with NADP or NADPH at neutral pH and high ionic strength, and dimeric at its optimal pH. Functioning G6PD is predominantly dimeric.

That many variants of G6PD have been discovered is not surprising, after what has been learned concerning amino acid substitutions in the hemoglobin molecule (Chapter 24). In contrast to the latter, however, the exact molecular abnormality of most of the variants is unknown. As yet, only the normal enzyme has been purified to a homogeneous, crystalline state and fingerprinted,<sup>101</sup> and only two variants, A<sup>101</sup> and Hektoen,<sup>103</sup> have been shown to be due to single amino acid substitutions.

G6PD may be subjected to electrophoresis on a variety of media and the position of the enzyme can be determined by application of a reaction system that results in precipitation of a dye or the appearance of a fluorescent band at the point to which the enzyme has migrated.<sup>5</sup> The concentration of substrate at which the enzyme manifests one half of its maximum velocity (the Michaelis constant,  $K_m$ , of the enzyme) may be determined, as well as activity at different pH levels, rate of denaturation by heat, and capacity to utilize different substrate analogues. Based on such measurements, standardized methods for characterization of G6PD have been agreed upon internationally,<sup>100</sup> an international reference laboratory has been established, and a standard nomenclature has been recommended.<sup>3</sup>

The genotypic and phenotypic symbol is Gd, that for the enzyme itself is G6PD.<sup>3</sup> The normal enzyme is designated B or B\*, the

plus sign indicating normal enzymatic activity (65 to 150%). This is the most common enzyme found in all population groups studied. Another common variant, A<sup>+</sup>, the one found to be especially prevalent in Negroes, migrates faster than B on electrophoresis. Type A<sup>-</sup> is the most common, clinically significant, abnormal form of G6PD in Negroes. The minus sign indicates enzyme activity of 25% or less. To designate 25 to 65% activity the sign  $\pm$  was proposed, and for greater than 150%, ++, but these signs have only been used in association with the letter designations. Furthermore, they are somewhat misleading in that the enzyme present in the erythrocytes of Gd<sup>A</sup> individuals, although structurally different from the normal, was found to be enzymatically as active as normal G6PD, but fewer active molecules could be detected. In addition, the abnormal enzyme is produced at the same rate as the normal enzyme so that the youngest erythrocytes and

the nucleated red cells of the enzyme-deficient individuals display normal enzyme activity.<sup>101,103</sup> Thus, the greatly reduced activity refers to the red cells of non-anemic individuals, very few of which are young corpuscles. This explains the clinical manifestations of G6PD deficiency in GD<sup>A-</sup> persons (Fig. 23-2).

B and A are the only letter designations for G6PD variants. All other variants are designated by geographical or trivial names (Table 23-1). The common variant with deficient activity in Caucasians is Gd Mediterranean; a variant found among Chinese is Gd Canton.<sup>63</sup> Other common variants<sup>107</sup> are Gd Markham (New Guinea), Gd Taiwan-Hakka (Hakka-Chinese), Gd Union (Philippines),<sup>106</sup> Gd Campbellpur (Pakistan), Gd Debrousse<sup>34</sup> (Arab), Gd Athens (Greece),<sup>60</sup> and perhaps also Gd Corinth (Greece, Mediterranean, S.E. Asia), and Gd Panay (Philippines).<sup>37</sup>

*Increased enzyme activity ("Class 5")*

<i>Electrophoretically fast</i>
Hektoen <sup>11</sup>

The variants are listed in five classes according to degree of enzyme activity and the associated clinical manifestations. In addition, each is subdivided according to electrophoretic mobility and under that category, the variants are listed alphabetically and the most common ones are shown in bold face type. Where no references are given, they will be found in Bull WHO<sup>107</sup> in which the reported values for electrophoretic mobility,  $K_m$ , heat stability, etc., are tabulated. Also noted in the same issue are additional variants for which insufficient data have been provided to warrant their inclusion in the above tabulation. In addition are listed the following variants thought to be identical with one of the variants given in the table: Hong Kong 2, Johnstown, Jobit, Loyola (D-), Nashville 2, New Guinea II, Panay-like, Seattle-like, Singapore, U-M<sup>72</sup>

Organization a table listing the biochemical properties of the above-named common forms together with an additional 66 rare variants, for a total of 78 variants, was published<sup>107</sup> and a number of other reported variants, insufficiently described, or possibly identical to variants named previously, were recorded. Still other variants have since been

reported.<sup>46, 47, 69, 76</sup> About half the reported variants have normal or only slightly reduced enzymatic activity in red cells and are not associated with clinical manifestations. These include B\* and A\*. Another group of variants is associated with severe deficiency of enzymatic activity in the red cells, and may or may not require exogenous agents such as

drugs, infections, or fava beans for hemolysis to occur. These include Gd Markham, Gd Union, Gd Campbellpur, Gd Mediterranean, Gd Corinth, and Gd Panay.<sup>37</sup> In still another group the enzymatic deficiency is moderate or mild. This group includes Gd<sup>A</sup>, in which exposure to an oxidant usually is the only circumstance leading to the occurrence of hemolytic anemia, and also Gd Debrousse, Gd Canton, and Gd Athens. About 20 variants are associated with enzymatic deficiency which is not necessarily more than moderate, but chronic nonspherocytic hemolytic anemia is present nevertheless, even in the absence of exogenous agents. These variants include Gd Manchester, Gd Alhambra,<sup>7</sup> and Gd Tripler.<sup>31</sup> One variant, Gd Hektoen,<sup>31</sup> has increased activity.

Some idea of the frequency of rare as compared with common variants of G6PD is gained from a survey of 735 male African Bantus, among whom an average of 63% G6PD B<sup>+</sup> was found, 17% G6PD A<sup>+</sup>, 19% G6PD A<sup>-</sup>, and 1.2% rare variants, which included four probable new ones (G6PD Inhambane, G6PD Chibuto, G6PD Lourenzo Marques, and G6PD Manjacaze).<sup>78</sup>

In the Negro (Gd<sup>A</sup>), G6PD deficiency is largely confined to the erythrocytes, but in Caucasian mutants the defects involve many other tissues, including leukocytes<sup>14,73</sup> and platelets.<sup>74</sup> In one female patient with G6PD deficiency and hemolytic anemia, fatal sepsis was associated with inadequate bactericidal activity resulting from defective PPP shunt activity.<sup>28</sup>

### Mechanisms of Hemolysis

The critical role that reduced glutathione (GSH) plays in red cell metabolism (Chapter 3) makes it necessary for the red cell to be capable of rapidly regenerating GSH whenever it has been oxidized. When this is possible, the erythrocyte can continuously absorb free radicals or peroxide derived from drugs or other sources without harmful consequences to the cell.<sup>55</sup> Administration of primaquine to Gd<sup>A</sup> subjects was observed to be associated with a decrease in the levels of

GSH in the erythrocytes, followed by acute hemolytic anemia. This occurred because the mutant A<sup>-</sup> enzyme, although enzymatically as active as normal G6PD, is more rapidly degraded during erythrocyte aging than is the normal enzyme.<sup>105</sup>

In Gd Mediterranean individuals, on the other hand, enzyme activity is significantly lower than normal even in the youngest red cells, and degradation during the aging of red cells is accelerated. Since the earliest observations on these two variants were made, many other variants and a variety of clinical syndromes associated with G6PD deficiency have been encountered, as already mentioned, but in many instances the degree of enzyme deficiency has not correlated well with the clinical manifestations. Thus, whereas the hemolytic manifestations in Gd Bat-Yam, Gd Ramat-Gan,<sup>75</sup> and Gd Worcester<sup>84</sup> subjects could be explained by the total absence of G6PD activity, and hemolysis in a Gd Oklahoma variant subject<sup>53</sup> could be attributed to a very low affinity of the variant enzyme for G6P (glucose 6-phosphate, Fig. 23-1), in other variant subjects, such as Gd Tripler,<sup>34</sup> Gd Manchester, and Gd Alhambra,<sup>7</sup> chronic hemolytic anemia was present even though neither very severe G6PD deficiency nor unusually high  $K_m$  values for substrate or coenzyme were present.<sup>104</sup> It is reasonable to conclude that enzyme activity and kinetic characteristics determined *in vitro* under unphysiologic conditions may provide misleading information concerning the physiologic activity of the enzyme in the variant cells. For example, whether or not variant enzymes generate enough NADPH in red cells to maintain an adequate concentration of reduced glutathione may depend on whether the enzyme is inhibited by physiologic concentrations of NADPH and by ATP.<sup>104</sup>

The exact reason why the life span of G6PD-deficient red cells is shortened is not known. Drug-induced hemolysis of such cells generally is accompanied by the formation of Heinz bodies (see Chapters 3 and 20) which become attached to the red cell membrane. The Heinz bodies may be produced as the

result of the formation of hydrogen peroxide through interaction of the chemical agent or its active derivative and oxyhemoglobin.<sup>24</sup> In the absence of adequate amounts of GSH, oxidative denaturation of the hemoglobin occurs and is followed by precipitation of globin. The precipitated globin becomes attached through disulfide bridges to membrane sulfhydryl groups<sup>43,56</sup> and appears as Heinz bodies. G6PD-deficient red corpuscles containing such inclusions encounter difficulties in passage through the spleen and perhaps elsewhere with resulting destruction, which occurs both in the spleen and liver.<sup>98</sup>

*Additional mechanisms, possibly involved* in the pathogenesis of hemolysis associated with infection or favism in G6PD-deficient subjects, and in neonates, will be discussed below.

### Clinical Manifestations

The clinical manifestations of G6PD deficiency may be episodic with complete clinical recovery in the intervening periods, as seen most typically in the Negro subjects exposed to primaquine whose illnesses first drew attention to this disorder; or they may be chronic, but often marked by periods of acceleration; or they may occur under conditions of stress associated with infection or drug administration; or they may appear in the neonatal period or after exposure to the fava bean.

### Drug-Induced Hemolytic Anemia

The typical event in Gd<sup>A-</sup> individuals is a self-limited hemolytic episode from which recovery occurs even if drug exposure is continued (Fig. 23-2). The clinical manifestations are those of an acute hemolytic anemia (Chapter 20) of moderate severity, together with the usual hematologic and pigmentary changes and the appearance of Heinz bodies. Abdominal or back pain may occur; the urine may turn dark, even black with hemoglobinuria; and then signs of erythrocyte regeneration appear, during which the Heinz bodies disappear, presuma-

bly because of sequestration and removal in the spleen. In addition to primaquine and pamaquine, a number of other reducing substances ("oxidant drugs") (Table 23-2), especially sulfonamides, cause hemolysis in G6PD-deficient individuals.

By tagging the red cells with radioactive chromium, it was shown<sup>30</sup> that sensitivity to the hemolytic effect of this drug was due to an intrinsic abnormality of the red corpuscles.

**Table 23-2. Compounds Reported to Have Been Associated with Increased Red Cell Destruction in Individuals with G6PD Deficiency<sup>9,14,97,110</sup>**

Antimalarials	Primaquine, pamaquine, pentamquine, quinocidine, quinacrine (Atabrin), quinine (C)
Sulfonamides	Sulfanilamide, sulfapyridine, salicylazosulfapyridine <sup>97</sup> (Azulfidine), sulfamethoxypyridazine (Kynex), sulfacetamide, N <sub>2</sub> -acetylsulfanilamide, 2-amino-5-sulfamylthiazole, sulfisoxazole (Gantisin)
Sulfones	Thiazolsulfone (Promizole), diaminodiphenylsulfone (DDS), sulfoxone (Dapsone) <sup>95</sup>
Nitrofurans	Nitrofurantoin (Furadantin), <sup>50</sup> furazolidone (Furoxone), furaltidone (Altafur), nitrofurazone (Furadin)
Antipyretics and analgesics	Acetanilid, aspirin, acetophenetidin (Phenacetin), antipyrine (C), aminopyrine (Pyramidon) (C)
Miscellaneous	Naphthalene (mothballs), <sup>29</sup> probenecid (Benemid), vitamin K (water soluble analogues) <sup>93</sup> , phenylhydrazine, isoniazid with or without para-aminosalicylic acid, trinitrotoluene, methylene blue, dimer-capitol (BAL), chloramphenicol (C), quinine (C), fava beans (C)

(C) denotes drugs that cause hemolysis in G6PD-deficient Caucasians but are not or are only slightly hemolytic in Gd<sup>A-</sup> Negroes

The sensitivity was noted to be self-limited for, after the initial hemolytic episode, the hemoglobin level returned to normal even though administration of the drug was continued (Fig. 23-2). Red corpuscles obtained from subjects who had undergone hemolysis and were still receiving the drug were no longer sensitive, as judged by the survival of the red cells following transfusion into a patient who had never before received primaquine. Nevertheless, when red cells from a primaquine-sensitive subject, withdrawn long after a hemolytic reaction, were transfused into a subject who had been pretreated with primaquine, the corpuscles were rapidly destroyed. Thus it became clear that, in primaquine-sensitive subjects, some red cells are sensitive and others are not. The nonsensitive ones predominate after a hemolytic reaction. Cohort labeling with  $^{59}\text{Fe}$  revealed that sensitivity was a function of red cell age and this in turn focused attention on the metabolism of the red cells, since it was well known that the activities of certain enzymes decline on aging. The discovery that the level of GSH in primaquine-sensitive cells is diminished and that the cells are unable to protect the GSH against oxidative stress<sup>8</sup> led to examination of the pathways of GSH reduction within the red cells of primaquine-sensitive individuals and the discovery that there was a deficiency of G6PD.<sup>19</sup>

In Gd Mediterranean individuals, whose enzyme deficiency is more severe than that of Gd<sup>A</sup> carriers, some drugs (Table 23-2) that rarely are harmful to Gd<sup>A</sup> carriers may cause red cell destruction, or may do so when given in smaller doses.<sup>68</sup> Furthermore, the hemolytic anemia may not clear spontaneously while drug therapy is continued, because the G6PD content of even the youngest cells is low in the Mediterranean variety. Individuals differ in the intensity of the clinical manifestations. Enzyme levels in heterozygous females have been found to range from very low to normal levels,<sup>97</sup> as might be expected on the basis of the X-inactivation hypothesis, so that sex does not exclude the possibility of a drug-induced hemolytic reaction due to G6PD deficiency.<sup>17</sup>

### *Episodic Hemolytic Anemia in the Absence of Drug Administration*

While certain drugs used in the treatment of infections may aggravate red cell destruction in patients with G6PD deficiency,<sup>62</sup> the opposite may also be true if the treatment relieves the infection.<sup>22,39</sup> What is especially noteworthy is the fact that, in the absence of drug administration, hemolytic episodes, in some cases quite severe<sup>81</sup> and even resulting in acute renal failure,<sup>96</sup> have been observed in G6PD-deficient individuals when they had bacterial or viral<sup>99</sup> infections, diabetic ketoacidosis,<sup>17</sup> acute<sup>26</sup> or chronic hepatitis,<sup>71,81</sup> or nephritis.<sup>17</sup> Such hemolytic episodes have been observed in Caucasians<sup>17,22,42</sup> as well as in Negroes, and in females as well as in males.<sup>17</sup> They have been attributed to the oxidative activity generated by naturally occurring substances, such as ascorbic acid, cysteine, and pyruvic acid,<sup>93</sup> to toxic products formed in the course of disease, or to hydrogen peroxide production by phagocytosing leukocytes.<sup>5</sup> The interesting observation has been made that hemolysis of enzyme-deficient erythrocytes was increased when these cells were exposed *in vitro* to influenza virus, as compared with normal cells.<sup>67</sup>

### *Favism<sup>49,60</sup>*

That exposure to the fava bean is toxic and can even be fatal to some individuals has been known, allegedly, since the time of Pythagoras. The onset of hemolysis is quite sudden. According to a study of 506 patients,<sup>49</sup> it may occur within a few hours following inhalation of the plant's pollen and within one or two days after ingestion of either fresh or dry fava beans. The majority of the 506 subjects were children two to five years of age; the male/female ratio was 6.2/1. The syndrome was severe, even in females, and hemoglobin levels as low as 4 g/dl, and even 1.8 g/dl were encountered.

It is clear that favism affects only individuals with G6PD deficiency<sup>94</sup> and especially those with the Mediterranean phenotype, but an additional factor seems to be required

since not all G6PD-deficient persons,<sup>45,88</sup> even sometimes in the same family, are susceptible. Immunologic factors,<sup>60</sup> pyrimidine derivatives in fava beans capable of oxidizing GSH,<sup>77</sup> an erythrocyte acid phosphatase phenotype,<sup>15</sup> and genetic diversity of the Mediterranean G6PD phenotype<sup>92</sup> have been suggested as causes of the susceptibility. Favism has not been reported in subjects with the A<sup>-</sup> type of G6PD deficiency. There is one report of favism from West China.<sup>33</sup>

### Neonatal Jaundice

Neonatal hyperbilirubinemia without evidence of immunologic incompatibility and unrelated to drugs given to mother or infant is relatively common in G6PD-deficient newborns in Greece,<sup>32</sup> Thailand,<sup>72</sup> and in infants with all genotypes of G6PD mutation in China<sup>67</sup> and elsewhere,<sup>37a</sup> but is rare in newborn Negroes.<sup>59</sup> The jaundice may be severe enough to require exchange transfusion. The susceptibility of G6PD-deficient infants to hemolysis has been attributed to their low blood sugar, "enzymatic immaturity," their low levels of red cell GSH peroxidase (page 789), and perhaps also to drugs, such as vitamin K, given when hepatic drug detoxifying systems are incompletely developed.

### Nonspherocytic Congenital Hemolytic Anemia

Some patients with Gd Mediterranean have chronic hemolytic anemia from infancy or childhood, although most develop hemolysis only under conditions of stress.<sup>10</sup> More usually this syndrome, which clinically is similar to that of nonspherocytic hemolytic anemia due to other causes (Chapter 20), is associated with rare enzyme variants, usually with very low activity or marked instability, such as those listed in Table 23-1, "Class I." In the reported subjects, osmotic fragility was normal and splenectomy was not beneficial. Most of the cases reported have been in Caucasians, but the Gd Charleston<sup>11</sup> and Gd San Diego<sup>41</sup> families were Negroes, as was a family with what might have been the Oklahoma variant.<sup>38</sup>

### Diagnosis and Differential Diagnosis

The clinical importance of G6PD deficiency is probably much greater than is generally appreciated. Furthermore, it is not generally recognized that infections can precipitate mild, and sometimes very severe,<sup>69</sup> hemolytic episodes and that small doses of certain drugs (Table 23-2) may do so in G6PD-deficient patients who have diabetic acidosis, pneumococcal pneumonia, hepatitis, streptococcal pharyngitis, chronic renal disease, malaria or other illnesses.<sup>97</sup> The degree of blood destruction differs considerably from one patient to another, and mild episodes of anemia should not be overlooked. In addition, if the hemolysis has been associated with an infection, reticulocytosis may not be as great as might otherwise be expected. Unless the diagnosis is obvious, the occurrence of a hemolytic episode is a reason for an appropriate test for G6PD deficiency to be performed, among other diagnostic steps (Chapter 20). The caution should be added that a blood enzyme assay, performed after a hemolytic episode, often will not detect G6PD deficiency even if present because the most deficient cells have been destroyed. Such patients need to be tested two to four months after the hemolytic episode.

The hematologic manifestations depend on the severity of the hemolytic episode and may range from slight polychromatophilia and little else, to spherocytosis and signs of red cell fragmentation. In the autohemolysis test (Chapter 20), a moderate increase in hemolysis above normal is found; this is only partially prevented by the addition of glucose or ATP. Heinz bodies should be demonstrable (page 736), but their presence is not specific evidence of G6PD deficiency. The possibility of unstable hemoglobin disease can be ruled out by heat stability or isopropanol stability tests (Chapter 24) and hemoglobin electrophoresis (Chapter 20).

Both screening procedures<sup>100</sup> and quantitative assays for G6PD have been described. The former<sup>5,66</sup> depend on either (1) the reduction of a dye (brilliant cresyl blue, methylene blue, etc), which can be observed visu-

ally; (2) the reduction of methylene blue linked to the reduction of methemoglobin (MHb reduction test)<sup>16,100</sup>; (3) the ascorbate-cyanide test, in which the browning of hemoglobin is observed when it is not protected from peroxidation; or (4) the spot test, involving the visual observation of fluorescence of NADPH formed in the G6PD reaction.<sup>4,6</sup>

In the *spot test*, blood is added to a reaction mixture containing saponin, buffer, glucose-6-PO<sub>4</sub>, and NADP. The mixture is spotted on filter paper after 5 to 10 minutes and is inspected under an ultraviolet hand lamp. This commonly used test,<sup>35</sup> a dye reduction procedure, is a fairly specific one and can be carried out on stored blood.

The *ascorbate-cyanide test*<sup>44</sup> utilizes intact red cells rather than hemolysates and for that reason is superior to other screening tests for the detection of the heterozygous state for G6PD deficiency. A tetrazolium-linked procedure<sup>36</sup> also is a practical and sensitive method for this purpose.

G6PD activity of cells can be estimated quantitatively<sup>68</sup> by adding a carefully measured amount of hemolysate prepared from washed, lysed red blood cells to an assay mixture containing buffer, glucose-6-PO<sub>4</sub>, and NADP, and measuring the rate of NADPH generation, as outlined by a WHO scientific group.<sup>100</sup> A cytochemical method also has been devised whereby, through the use of the tetrazolium salt Nitro-BT (NBT), a semiquantitative estimate of G6PD activity in single cells can be made.<sup>79</sup>

The detection of all female heterozygotes is not possible, but those with rather low enzyme levels who are likely to develop hemolytic episodes can be identified by the GSH reduction-inhibition test<sup>108</sup> or the MHb reduction test.<sup>16</sup>

## Treatment

The principles governing the treatment of acute and chronic hemolytic anemias are as applicable here as in hemolytic anemias due to other causes (Chapter 20). G6PD individuals should avoid drugs that might induce

hemolytic episodes (Table 23-2). Whether blood transfusion should be given depends on the rate of hemolysis. If the rate is very severe, as in some cases of favism, whole blood or packed red cells may be lifesaving. Splenectomy has not proved helpful in hemolytic anemia due to G6PD deficiency.

## Course and Prognosis

Unlike the hemolytic episodes in the A<sup>-</sup> type of G6PD deficiency, those occurring in the more severe Mediterranean type of deficiency may not terminate rapidly, but in the vast majority recovery does take place. When the course of the hemolytic process is prolonged, complications such as gallstones may develop, but other complications are unusual. There is little information regarding the ultimate prognosis of people affected with G6PD deficiency.<sup>70</sup>

Favism, however, stands apart. Without adequate treatment, death during a hemolytic episode may occur; fatalities were not uncommon at one time.

## Importance of Screening for G6PD Deficiency

Hemolytic anemia due to G6PD deficiency, as described above, can be severe and even life-threatening. Consequently, screening should be mandatory for all patients of certain ethnic groups on admission to a hospital since they may have illnesses or receive drugs that would produce hemolytic crises.<sup>66</sup> The Mediterranean variant is particularly sensitive. Screening also is desirable for populations of appropriate ethnic background who receive antimalarial prophylaxis. Although standard prophylaxis produces only mild hemolysis in G6PD-deficient Negroes, about 2% of those in the US Army develop severe hemolysis.<sup>66</sup>

It should also be noted that the use of G6PD-deficient blood for transfusion is potentially harmful since patients given such blood may receive drugs or suffer from illnesses that may lead to hemolysis of G6PD-deficient cells. Especially inadvisable is the

use of red cells from donors with the Mediterranean type of G6PD deficiency because a large proportion of such cells may be destroyed.

## Other Deficiencies Involving the HMP (PP) Pathway and GSH Metabolism

In addition to G6PD, deficiencies of four other enzymes involved in the HMP pathway or in GSH metabolism have been described.

### 6-Phosphogluconic Dehydrogenase (6PGD) Deficiency

It is not certain that the reported cases<sup>124</sup> of 6PGD deficiency (Fig. 23-1) represent hemolytic anemia due to this deficiency. In any event, the deficiency must be very rare and the clinical effects are poorly defined. Both partial<sup>116,138</sup> and complete<sup>137</sup> deficiency have been reported. Inheritance is autosomal and diagnosis is made by carrying out an assay for the enzyme.<sup>5</sup>

### Glutathione Reductase (GR) Deficiency

As discussed in Chapter 3 (page 103), because GR is a flavoprotein its activity depends in part on the dietary intake of riboflavin. Consequently, partial deficiency of red cell GR is relatively common. Whether GR deficiency was the cause of the many disorders with which it was found to be associated<sup>126,142</sup> is uncertain. However, restudy of the propositus of one large family following the addition of flavine adenine dinucleotide (FAD) suggested that a true, genetically determined deficiency of GR may exist.<sup>111</sup> Nevertheless it remains very doubtful whether drug-induced or spontaneous pancytopenias<sup>131</sup> or other hemolytic anemias<sup>121</sup> and a variety of reported hematologic disorders are etiologically related to GR deficiency.<sup>5</sup> Although a fluorescent spot screening test<sup>4</sup> will provisionally indicate decreased erythrocyte GR deficiency, definitive diagnosis depends upon specific enzyme assay.<sup>5</sup>

A GR variant was reported to be associated with gout.<sup>127</sup>

### Glutathione Peroxidase (GSH-Px) Deficiency

Erythrocytes from the healthy newborn infant have from 55<sup>117</sup> to 85%<sup>143</sup> of the mean GSH-Px activity found in the erythrocytes of adults.<sup>120,132</sup> Values for premature infants do not differ from those for term infants.<sup>117,120,143</sup> In some studies, adult levels were found to be achieved at 6 to 10 months,<sup>132,143</sup> but, in another series,<sup>117</sup> not until puberty. As contrasted with the erythrocytes of adults, erythrocytes of normal newborn infants form Heinz bodies and methemoglobin more readily upon exposure to low concentrations of hydrogen peroxide *in vitro*.<sup>120</sup> This has been attributed to their relative deficiency of GSH-Px, and has been correlated with a very mild, self-limited hemolytic process found in four newborn infants with a partial deficiency of GSH-Px.<sup>132</sup> Neonatal jaundice was reported to be associated with partial deficiency of GSH-Px in 12 infants.<sup>134</sup> In a large prospective study, however, relatively low levels of GSH-Px in newborn infants did not correlate with greater degrees of jaundice.<sup>143</sup>

In some of the families of the infants with neonatal jaundice, siblings or parents were found to have about 64% of normal adult GSH-Px activity.<sup>134</sup> This observation and the discovery of 70% of normal activity in the parents of a 17 year old boy who was found to have 36% of normal GSH-Px activity and had developed an acute hemolytic anemia associated with Heinz bodies in circulating erythrocytes following the transfusion of 3 units of autologous, stored blood<sup>133</sup> led to the postulate that GSH-Px deficiency is transmitted as an autosomal recessive.<sup>133,134</sup>

Circumstantial evidence favors some role for GSH-Px deficiency in the pathogenesis of transient hemolytic disorders, perhaps in relationship to drugs,<sup>134</sup> vitamin E deficiency in the newborn,<sup>117</sup> or other factors.<sup>143</sup> Menadione bisulfite, the vitamin K analogue,

which may be given to mothers during labor or to the newborn, inactivates GSH-Px.<sup>111</sup> In two adults, partial deficiency of GSH-Px was associated with an anemia which occurred following the administration of sulfonamides and had a hemolytic component.<sup>113</sup> However, in view of reports of deficiency of GSH-Px in apparently unrelated conditions (in the erythrocytes of iron-deficiency anemia,<sup>139</sup> and of liver disease with acanthocytosis,<sup>119</sup> as well as in the platelets of three unrelated patients with Glanzmann's thrombasthenia<sup>122</sup>) one must be cautious about assigning in all the reported cases a pathogenetic relationship between GSH-Px activity and hemolytic disorders.

Various methods for the measurement of GSH-Px have been described<sup>120,129,131</sup> but most consider the assay method of Paglia and Valentine<sup>130</sup> to be the best.

### Glutathione Deficiency

First discovered in Holland,<sup>135</sup> GSH deficiency has since been reported from France,<sup>112</sup> Switzerland,<sup>125</sup> and the United States.<sup>130</sup> The defect may be transmitted as an autosomal recessive trait,<sup>130</sup> but dominant-autosomal inheritance also has been reported.<sup>125</sup> As described in Chapter 3 (page 104), GSH synthesis takes place in two steps. In two cases the defect was found to involve the second step, GSH synthetase,<sup>112,130</sup> but in another the defect resided in the first step, namely,  $\gamma$ -glutamyl-cysteine synthetase.<sup>125</sup> The clinical manifestations are those of a nonspherocytic congenital hemolytic anemia and accentuation of hemolysis may take place during drug administration. In the patient with GSH synthetase deficiency, both the Heinz body test and the cyanide-ascorbate test gave positive reactions.<sup>130</sup> GSH deficiency is diagnosed by measuring the content of the tripeptide in red cells,<sup>110</sup> but localization of the enzyme defect in one of the two steps of GSH synthesis requires specific enzyme assays which are not carried out in clinical laboratories.<sup>112,123</sup>

## History

The story of the growth of knowledge of the hemoglobinopathies and thalassemia pro-

vides a fascinating picture illustrating the value of the pursuit of knowledge for its own sake. It reveals the fruits that can be gained if curiosity is aroused and an answer sought to questions that may at the time seem to be of no practical importance, as well as the progress that can be made when the right question is put to a "prepared mind."

In 1910, James B. Herrick<sup>2</sup> reported "peculiar, elongated, sickle-shaped red corpuscles" in "a case of severe anemia" in a Negro. He described the clinical manifestations in his patient in considerable detail. The sickle cells, he thought, were freakish poikilocytes, and, with considerable prescience, suggested that they were a manifestation of a peculiar chemical or physical condition. Emmel, in 1917, observed the transformation of the biconcave disc to the sickle form *in vitro*.<sup>3</sup> He also noted that sickling occurred both in persons with severe anemia and in others who were apparently healthy, thus recognizing both sickle cell anemia and sickle cell trait.

The comprehensive studies of Hahn and Gillespie in 1927<sup>4</sup> delineated the conditions affecting sickle cell formation *in vitro*, including pH, temperature, fixatives, tonicity and others. Among the most important of

their observations was that exclusion of oxygen was a prerequisite to sickling and that the phenomenon could be reversed on reexposure to the gas. They postulated that similar effects of oxygen could occur in vivo, hypoxia leading to cellular distortion with consequent hemolysis. Later, Hahn applied the term "sickle cell trait" to the asymptomatic condition associated with in vitro sickling. He performed family studies and concluded that the trait was inherited as a dominant character.

Paralleling these events was the report of Cooley and Lee, in 1925, who separated from the complex of disorders of infancy and childhood that had been known as von Jaksch's anemia a syndrome characterized by chronic, progressive anemia commencing early in life, with pronounced erythroblastosis in the blood, a characteristic facies, splenomegaly, and a familial incidence.<sup>2</sup> The observation that these patients were of Mediterranean background led to the introduction of the name "thalassemia," derived from the Greek word for sea. The parents of these children, unfortunately, were not examined. At this time and in the following years, descriptions appeared in the Italian literature of a milder disorder, encountered in adults as well as children, which was marked by morphologic abnormalities in the red cells and evidence of increased hemolysis, in spite of decreased red cell osmotic fragility (microcytopenic anemia, *malattia di Rietti-Greppi-Micheli*). In 1938, Caminopetros noted that the parents of a child suffering from severe thalassemia had diminished red cell osmotic fragility,<sup>3</sup> but even then the true relationship between Cooley's anemia and the Rietti-Greppi-Micheli syndrome was not appreciated.

Curiosity regarding the significance of basophilic stippling of the red cells of several adult patients with minor ailments led to the description in 1940 by Wintrobe and his associates of what they considered to be a mild form of Cooley's anemia.<sup>12</sup> These investigators also showed that the manifestations of this disorder were present in both parents of a child with classic Cooley's

anemia. Subsequent formal genetic studies established that Cooley's anemia is the homozygous state for a partially dominant autosomal gene, the patients described by Rietti and by Wintrobe and their co-workers representing the heterozygous state.<sup>10</sup>

In 1940, the sickling phenomenon was re-investigated by Sherman,<sup>9</sup> who confirmed the observations of Hahn and Gillespie regarding reversibility and the importance of oxygen. Sherman also found that the cells in sickle cell disease were birefringent, an observation that aroused curiosity but remained unexplained for nearly a decade. Then, in a casual conversation, the birefringence was called to the attention of the physical chemist, Linus Pauling.<sup>11</sup> Pauling conceived the possibility that interaction between abnormal hemoglobin molecules might explain this phenomenon. With Itano, he demonstrated an electrophoretically abnormal hemoglobin in sickle cell anemia,<sup>8</sup> thus originating the concept of molecular disease.

In the same year that Pauling made his discovery, Neel published a report of elegant genetic studies establishing that sickle cell trait was the heterozygous and sickle cell anemia the homozygous state for the same gene.<sup>7</sup> With the demonstration by Ingram of a difference in the amino acid sequence in one small part of the polypeptide chains of sickle cell hemoglobin,<sup>6</sup> the science of molecular biology took root. The contributions of Perutz, Lehmann, and many others have resulted in an expansion of knowledge to a degree unforeseen even in the 1950's, let alone when Herrick wrote about his patient with a peculiar anemia.

### Definitions

Inherited abnormalities of hemoglobin synthesis may be divided into two groups: those associated with structurally abnormal hemoglobin variants and those in which one or more of the normal hemoglobin polypeptide chains are synthesized at a markedly reduced rate. The term "hemoglobinopathy" will be restricted to the former disorders and the term "thalassemia" to the latter. Included

with the thalassemias are certain disorders in which structurally abnormal hemoglobins are formed from normal chains or parts of normal chains, such as Hb H ( $\beta_4$ ), Hb Bart's ( $\gamma_4$ ), and Hb Lepore. Hemoglobin Constant Spring also is included with the thalassemias because of the clinical picture it produces (page 881).

## Etiology and Pathogenesis

### Structure of the Abnormal Hemoglobins

The structure of normal hemoglobin is discussed in Chapter 4 (page 172) and the amino acid sequence of the normal  $\alpha$ -,  $\beta$ -,  $\gamma$ -, and  $\delta$ -chains is given in Table 4-7 (page 174).

The great majority of abnormal hemoglobins differ from the normal in that a single amino acid has been substituted for another. In hemoglobin S, for example, valine has replaced glutamic acid as the sixth amino acid from the N-terminal end of the  $\beta$ -chain. Many other examples of this kind of substitution have been described. These are listed in Table 24-1 according to whether the mutation has affected the  $\alpha$ -chain, the  $\beta$ -chain, the  $\gamma$ -chain, or the  $\delta$ -chain. Many more  $\beta$ -chain variants than  $\alpha$ -chain variants have been reported, possibly because serious abnormalities of the  $\alpha$ -chain might be expected to cause early fetal death, thereby making their discovery less likely. Since fetal hemoglobin ( $\alpha_2\gamma_2$ ) does not contain  $\beta$ -chains, an abnormal  $\beta$ -chain is unlikely to produce fetal death and therefore has a greater chance to persist until its subject has reached an age at which the disorder will be detected. The paucity of reported  $\gamma$ - and  $\delta$ -variants presumably reflects the fact that structural alterations in these chains are not apt to produce a disease state that would bring them to the attention of a physician.

In a small group of hemoglobins, the abnormalities are more complex than amino acid substitution (Table 24-2). Two amino acid substitutions are present in HbC Harlem, HbC Georgetown, and HbJ Singapore,

and three in Hb Hopkins 2-II.<sup>106</sup> Extra amino acids have been added to the C-terminal ends of hemoglobins Constant Spring<sup>86</sup> and Tak,<sup>90</sup> whereas Hb Wayne not only has additional amino acids, but also has an altered sequence affecting the C-terminal residues.<sup>117</sup> The Lepore hemoglobins (Chapter 26) are those in which the non- $\alpha$ -chain is a hybrid formed from the N-terminal portion of the  $\delta$ -chain and the C-terminal portion of the  $\beta$ -chain. "Anti-Lepore" hemoglobins (Chapter 26), ie, with a  $\beta$ -N-terminal and a  $\delta$ -C-terminal, have also been described; eg, Hb Miyada and HbP Congo.<sup>47</sup> A possible  $\gamma\beta$  hybrid, Hb Kenya, has been reported.<sup>95</sup> Deletions of one or more amino acids are found in several hemoglobins (Table 24-2). Finally, some hemoglobins are tetramers, ie, all four polypeptide chains are identical. The genetic mechanisms leading to these complex changes are discussed in a later section (page 797).

### Nomenclature

When newly discovered hemoglobins were first reported, they were designated by letters of the alphabet. Normal adult hemoglobin and fetal hemoglobin were called HbA and HbF, respectively. When sickle cell hemoglobin was discovered, some called it HbB, but soon the letter S was assigned to it, and, to avoid confusion, no other hemoglobin was designated B.<sup>36</sup> Hemoglobins associated with methemoglobinemia were given the letter M.<sup>55</sup> Other hemoglobins were assigned letters in alphabetical order. By the time the letter Q was reached, it had become apparent that this system would not provide enough designations. Furthermore, structurally different hemoglobins occasionally had been given the same letter. In 1960 a new system of nomenclature was adopted, and the letters R and T through Z were left unassigned.<sup>38</sup>

New hemoglobins are now given geographic names, and it is left to the discoverer to choose the most appropriate one. The name may be a city, district, province, hospital, etc, and may be the native region of the propositus or the place of discovery. Capital

letters are sometimes retained to indicate the electrophoretic mobility most nearly approximated by the hemoglobin variant. Thus, the designation "HbG Copenhagen" indicates a hemoglobin discovered in Copenhagen and found to have the same electrophoretic mobility as that of other hemoglobins G.

The nomenclature also provides for an abbreviated designation that indicates the nature of the structural abnormality insofar as it is known. Hemoglobin A is represented as  $\alpha_2\beta_2^A$  (see Chapter 4, page 172). When the abnormal chain has been determined, the name is substituted for the superscript of the abnormal chain, as  $\alpha_2\beta_2^{Punjab}$ . When the abnormality can be localized to a particular tryptic peptide (page 810), the designation becomes  $\alpha_2\beta_2^{T_{p1}}$ , indicating that the first tryptic peptide of the  $\beta$ -chain is defective. When the amino acid substitution in the abnormal peptide is known, it is indicated; eg,  $\alpha_2\beta_2^{T_{p1} \text{ Glu} \rightarrow \text{Val}}$ . Finally, when the nature and location of the substitution have been defined precisely, the abbreviation indicates the position (sequential number) and name of the substituted amino acid. Thus, HbS is designated  $\alpha_2\beta_2^{S_{65} \text{ Val}}$  or  $\alpha_2\beta_2^{S_{65} \text{ Glu} \rightarrow \text{Val}}$ . Many investigators now also include in parentheses the helical designation (Chapter 4) for the site of amino acid substitution, in which case HbS might be indicated by the formula  $\alpha_2\beta_2^{S_{65}(\text{A3}) \text{ Glu} \rightarrow \text{Val}}$ .

## Genetics

### Allelism and Linkage

By means of hybridization of radioactive mRNA with human chromosomes in metaphase, it was demonstrated that there are two chromosomal loci involved in hemoglobin synthesis, one on chromosome 2 and another on a B group chromosome (number 4 or 5)<sup>110</sup> (see Fig. 2-3, page 45). From the size of the two loci, it was concluded that the  $\alpha$ -chain structural genes occupy the locus on chromosome 2, whereas the  $\beta$ -,  $\gamma$ -, and  $\delta$ -structural genes occupy the B group locus.

That the  $\alpha$ -locus includes two separate, non-allelic, possibly reduplicated, structural

genes was suggested<sup>101</sup> to explain the generally lower proportion of abnormal hemoglobin found in patients with  $\alpha$ -chain variants (see below), the relatively mild nature of  $\alpha$ -thalassemia minor, and certain puzzling aspects of the inheritance of hemoglobin H disease<sup>121</sup> (Chapter 26). This concept has been supported by the detection of three structurally different  $\alpha$ -chains in members of three different families.<sup>84,92,106</sup> However, the absence of normal  $\alpha$ -chains in patients homozygous for Hb J Tongariki is difficult to explain on this basis.<sup>81</sup>

Genetic evidence indicates that the  $\beta$ - and  $\delta$ -genes are closely linked<sup>93,103,112</sup> and such linkage is further supported by the occurrence of asymmetric crossovers (page 874) between these genes, forming hemoglobins of the Lepore and Miyada type (Table 24-2; also Chapter 26). It is also likely that the  $\gamma$ -locus is near the  $\beta\delta$ -locus, since a  $\gamma\beta$ -hybrid, hemoglobin Kenya, has been reported.<sup>95</sup> There is good evidence that there are at least two non-allelic, structural  $\gamma$ -genes, one for a fetal hemoglobin designated  $G_\gamma$  ( $\gamma 136$  [H14] glycine) and another for one called  $A_\gamma$  ( $\gamma 136$  [H14] alanine).<sup>113</sup> These hemoglobins are found in normal cord blood in a  $G_\gamma$  to  $A_\gamma$  ratio of 3:1. Evidence from the observed  $\beta\delta$  and  $\gamma\beta$  crossovers suggests that the chromosomal arrangement of genes is  $G_\gamma A_\gamma \beta \delta$ .<sup>95</sup>

All genes for abnormal  $\beta$ -chain variants are alleles,<sup>105</sup> i.e., genes that occupy the same genetic locus. Furthermore, the genes producing  $\beta$ -thalassemias and hereditary persistence of hemoglobin F are either allelic or very closely linked (pseudoallelic) with those producing the  $\beta$ -chain structural variants.<sup>87,103,115</sup> Similarly, the genes producing  $\alpha$ -chain structural abnormalities and the  $\alpha$ -thalassemias probably are alleles. However,  $\alpha$ - and  $\beta$ -chain abnormalities are not alleles, nor are they linked.<sup>97,119,123</sup>

### Patterns of Inheritance

The abnormal hemoglobin diseases are inherited in a fashion sometimes referred to as "autosomal codominant." If the properties of the hemoglobin are such that symptoms

are produced in the heterozygous state, as in unstable hemoglobin disease, then the pattern of inheritance of the "disease" will be that of an autosomal dominant trait. If, on the other hand, only the homozygous condition is symptomatic, as in sickle cell anemia, a recessive inheritance pattern is observed and the heterozygous state is called the "trait." Whether symptomatic or not, the heterozygous state is detectable by means of hemo-

globin analysis. The expected inheritance patterns with various matings between heterozygous and homozygous individuals are given in Table 24-3.

A patient carrying two different abnormal hemoglobin genes is referred to as *doubly heterozygous*. The inheritance pattern in such situations may take one of two possible forms, depending on whether the two genes are alleles or non-alleles; i.e., whether they

Table 24-3. Expected Inheritance Pattern with Certain Matings

Parent A	Parent B	Expected Proportion of Children		
		Normal (%)	Heterozygous (%)	Homozygous (%)
Heterozygous	Normal	50	50	0
Heterozygous	Heterozygous	25	50	25
Homozygous	Normal	0	100	0
Homozygous	Heterozygous	0	50	50
Homozygous	Homozygous	0	0	100

 From Lee<sup>100</sup> courtesy of the author and Harper & Row

affect the same polypeptide chain or different ones (Table 24-4). For example, a man doubly heterozygous for Hbs S and C, both of which are  $\beta$ -chain defects and therefore allelic, passes one, and only one, of these genes along to his children.<sup>111</sup> All children, therefore, will be heterozygous for either Hb S or Hb C, but none will be normal and none will be doubly heterozygous. Non-allelic inheritance, when one gene affects the  $\alpha$ -chain and one the  $\beta$ -chain, is quite different, as has been observed in several families.<sup>119,123</sup> In such pedigrees, children of the doubly heterozygous patient may be normal, or they may inherit either or both abnormal genes.

Because of their close linkage,  $\delta$ -chain abnormalities tend to be inherited with a  $\beta$ -chain abnormality on the same chromosome (cis), but if on opposite chromosomes (trans) they will not be inherited together.<sup>93,112</sup>

### Hemoglobin Patterns Associated with Various Genetic Constitutions

The homozygous state has been observed with hemoglobins S, C,<sup>120</sup> D Punjab,<sup>85</sup> E,<sup>102</sup> and G Accra,<sup>88</sup> all of which are  $\beta$ -chain variants, and with J Tongariki,<sup>81</sup> an  $\alpha$ -chain variant. Such patients are unable to make hemoglobin A. Hemoglobins A<sub>2</sub> and F are qualitatively normal in homozygous  $\beta$ -chain disorders, but increased amounts of HbF often persist into adult life and the proportion of HbA<sub>2</sub> often is slightly increased.<sup>94</sup> In homozygous  $\alpha$ -chain disease, the hemoglobin A<sub>2</sub> component is qualitatively abnormal since it contains the abnormal  $\alpha$ -chain.

Most of the abnormal hemoglobins have been observed in the heterozygous state. In such patients, HbA usually predominates and the abnormal hemoglobin constitutes less than 50% of the total, usually about 20 to 40%. Exceptions to this rule include many

 Table 24-4. Allelic and Non-Allelic Inheritance Patterns in Doubly Heterozygous Individuals<sup>111,119</sup>

Patient	Spouse	Expected Proportion of Children		
		Normal	Heterozygous	Doubly Heterozygous
Two genes affecting same chain (allelic), eg. HbS and C	Normal	0	100% (50%S 50%C)	0
Two genes affecting different chains (non-allelic), eg. HbS Hopkins II	Normal	25%	50% (25%S, 25% Hopkins II)	25%

members of the hemoglobin J group, in which more than 50% of the hemoglobin may be abnormal, possibly because the abnormal fraction is contaminated with hemoglobin A<sub>2</sub><sup>116</sup> (Chapter 4, page 172). The reasons for the usually low proportion of abnormal hemoglobin are not known, but one possibility is that the abnormal chain is synthesized less rapidly than the normal.<sup>83</sup> Another is that cells with varying proportions of the normal and abnormal hemoglobins are released from the marrow and that those with the higher proportions of abnormal hemoglobin are more rapidly destroyed than the others.<sup>48</sup> In unstable hemoglobins, precipitation and splenic removal also may reduce the circulating amount of abnormal hemoglobin.

As a general rule, the proportion of abnormal hemoglobin in heterozygotes with  $\alpha$ -chain defects is lower than in those with  $\beta$ -chain defects. In the former, the abnormal hemoglobin constitutes an average of 23% of the total, whereas in the latter an average of 38% has been found.<sup>116</sup> This phenomenon is observed even when  $\alpha$ - and  $\beta$ -variants have homologous substitutions, such as those in Hb J Oxford ( $\alpha$  A13 Gly  $\rightarrow$  Asp) and Hb J Baltimore ( $\beta$  A13 Gly  $\rightarrow$  Asp). This fact might be explained by the presence of a total of four structural  $\alpha$ -genes (see above), only one of which is a mutant in the usual heterozygote.

In patients heterozygous for  $\beta$ -chain variants the proportion of HbA<sub>2</sub> may be slightly increased,<sup>84,121</sup> but the HbA<sub>2</sub> and HbF fractions are qualitatively normal. In contrast,  $\alpha$ -chain abnormalities affect the minor hemoglobin fractions as well as the major. Thus, in infants, as many as six hemoglobins may be detected: Hb A, Hb A<sub>2</sub>, and Hb F, along with three corresponding abnormal hemoglobins containing the mutant  $\alpha$ -chain.<sup>122</sup>

The hemoglobin pattern in doubly heterozygous individuals depends on whether the two abnormal genes are alleles or not. When they are allelic, as in hemoglobin SC disease, no hemoglobin A is made. Two abnormal hemoglobins (eg, HbS and HbC) are found in the circulation in approximately equal amounts and, in addition, there may be some

compensatory increase in hemoglobin F. In non-allelic double heterozygotes, four variants of adult hemoglobin will circulate. Such individuals can synthesize  $\alpha^A$ ,  $\alpha^X$ ,  $\beta^A$ , and  $\beta^Y$ -chains (X and Y superscripts indicating the mutant chains) and can form the following four hemoglobins:  $\alpha^A\beta^A$  (HbA),  $\alpha^X\beta^A$  (HbX),  $\alpha^A\beta^Y$  (HbY) and  $\alpha^X\beta^Y$  (HbXY). Such a pattern has been reported in a number of instances.<sup>82,96,113,114</sup>

### Genetic Events Leading to Abnormal Hemoglobins

The most common genetic alteration resulting in an abnormal hemoglobin molecule is presumed to be a *point mutation*, ie, the substitution of a single DNA nucleotide base for another. This alters the genetic code, often in such a way that an amino acid change occurs in the resulting globin. When the amino acid substitutions in the reported human hemoglobin variants were examined in relation to the genetic code, all such variants were found to be explainable by a change in only one of the three bases coding for each amino acid.<sup>48</sup> Substitutions that cannot occur by such an alteration have not been observed. For example, the substitution Asp  $\rightarrow$  Lys does not occur because neither of the codons for aspartic acid (GAC, GAU) can change to a codon for lysine (AAA, AAG) without altering two bases.

Only one possible exception to the one-base change rule has been noted.<sup>32,48</sup> In HbM Milwaukee, the change at  $\beta 67$  is Val  $\rightarrow$  Glu; in Hb Bristol it is  $\beta 67$  Val  $\rightarrow$  Asp. None of the known valine codons (GUU, GUC, GUA, and GUG) could change to both a glutamic acid codon (GAA, GAG) and an aspartic acid codon (GAU, GAC) by means of one-base changes. Thus, two possibilities exist: (1) either HbM Milwaukee or Hb Bristol occurred as a result of a double mutation, or (2) the  $\beta 67$  valine codon in normal globin mRNA is variable.

Lehmann and Carrell have estimated the one-base mutation rate at the hemoglobin locus at 1 in  $10^4$  individuals per generation.<sup>48</sup> At least 20 families have been recorded in which a spontaneous mutation probably occurred.<sup>32</sup>

Two types of point mutations have been defined. A *transition* is a substitution of a pyrimidine for another pyrimidine or a purine for another purine. A *transversion* is a substitution of a purine for a pyrimidine or vice versa. The amino acid changes produced by transversions tend to result in more radical alterations in protein structure than those occurring with transitions. If mutations occurred at random, twice as many transversions as transitions should be observed. However, the number of human hemoglobin variants resulting from transitions are about equal to those resulting from transversions.<sup>48</sup> If only substitutions affecting the molecular surface are tabulated, the expected 2:1 ratio is found, but changes in the molecular core are only rarely produced by transversion. Purine transitions are more common than pyrimidine transitions, and the most common of all point substitutions is adenine → guanine in DNA (guanine → adenine in RNA). Bunn found that 25 of 114 known hemoglobin variants arose from this mutation.<sup>32</sup> The reasons for the non-random nature of these genetic events are not entirely clear.

The mutation leading to Hb Constant Spring might have been a simple point substitution in a "stop" codon.<sup>85</sup> This unusual hemoglobin has 31 residues added to the normal  $\alpha$ -chain, and the first "extra" residue is glutamic acid (codons: GAA, GAG). The glutamic acid residue could have arisen from a one-base change in either of the two codons (UAG, UAA) that code for chain termination. Hemoglobin Tak, which has extra residues on the end of the  $\beta$ -chain, cannot be explained by a similar change; the first extra amino acid is threonine, and its codons (ACC, ACU, ACA, AGG) cannot arise from any of the "stop" codons by a one-base change.<sup>90</sup> It has been suggested that the normal  $\beta$ -chain may be longer than 146 amino acids when first synthesized and that one or more residues are lost by hydrolysis. If so, Hb Tak might then represent a stop codon mutation.

Genetic crossovers between chromosomal pairs also have the potential for generating abnormal hemoglobins. The usual crossovers occur at identical loci on the chromosome

pairs; these are called "homologous" or "equal" crossovers. Such a crossover in an individual carrying genes for HbS ( $\beta^6$  Val) and Hb Korle Bu ( $\beta^{73}$  Asn) is a possible way to form the gene for Hb C Harlem, carrying both substitutions.<sup>99</sup> Unequal or non-homologous crossing over (chromosomal mutation) has the potential for producing extensive changes in structural genes, such as deletion of a portion of the gene, as well as an addition to it or a fusion of genes at the crossover sites.<sup>101</sup> The hemoglobins with single or multiple deletions (Table 24-2) probably arose in this way since a minimum of three nucleotide bases must have been deleted. Furthermore, the "fusion genes" resulting in hemoglobins of the Lepore, Miyada, or Kenya type (Table 24-2) almost certainly were formed by unequal crossing over (see Fig. 26-9, page 874), and a similar mechanism may have resulted in Hb Hopkins 2-II<sup>106</sup> (Table 24-2).

One unusual hemoglobin may have been induced by a "frameshift" in the genetic code. If a single DNA base is added or deleted, all tripler codons distal to the change will be altered. The effects of such a change are most drastic when they occur toward the beginning of the polypeptide chain, since everything beyond the frameshift is "nonsense." Toward the end of the chain, however, the change might be tolerated. The amino acid sequence in Hb Wayne includes altered terminal residues and added amino acids,<sup>117</sup> and inspection of the possible codons supports the hypothesis that a frameshift due to a base deletion could account for the observed sequence.

The genetic mechanisms resulting in thalassemias and the formation of the tetrameric hemoglobins are discussed in Chapter 26.

### Molecular Pathology and the Functional Classification of Abnormal Hemoglobins

The careful construction by Perutz and co-workers of a three-dimensional model of the hemoglobin molecule<sup>109</sup> (Chapter 4) has made it possible to visualize the effects of amino acid substitution on molecular func-

tion.<sup>108</sup> The Perutz model demonstrates that the water-free, molecular core is stabilized by nonpolar interactions of the Van Der Waals type. Amino acids with polar side chains are completely excluded from the interior and are found only on the molecular surface, where they interact with water, rendering the molecule soluble. The heme group is covalently bound at the F8 histidine, but also forms about 60 contacts with nonpolar amino acids in the heme crevice, thereby contributing to the stability of the tertiary structure. This nonpolar environment makes possible the association of heme iron with oxygen without significant methemoglobin formation. The contacts between the four polypeptide chains in each molecule were also evaluated from the model, and found to be of two kinds. The larger contact, called  $\alpha_1\beta_1$ , is formed from nonpolar interactions among 34 amino acids; the smaller,  $\alpha_1\beta_2$ , involves only 19 amino acids (see Chapter 4). With oxygenation, the  $\alpha_1\beta_2$  contact undergoes significant alteration, a movement of about 0.7 nm (7 Å) or so taking place, producing so-called heme-heme or subunit interaction. This and other stereochemical changes involved in oxygen binding have been discussed by Perutz.<sup>107</sup> With this general background, the effects of substitution at certain molecular sites can be un-

derstood and a functional classification<sup>91</sup> of the abnormal hemoglobins can be made (Table 24-5).

Substitutions at the *molecular surface* usually are innocuous because they are not likely to affect tertiary structure, heme function, or subunit interaction. Indeed, most functionally normal hemoglobin variants, which produce no symptoms, are characterized by substitution at surface positions. Most of them have been discovered by means of hemoglobin electrophoresis in population screening studies and, therefore, result from substitutions that change the net charge of the molecule. Some surface substitutions result in hemoglobin molecules that tend to polymerize or *aggregate*. It is likely that such mutations create a site on the molecular surface that can interact with a complimentary site on an adjacent molecule. The exact nature of these molecular interactions is unknown, but some hypotheses are discussed in Chapter 25. The aggregating hemoglobins, of which Hb S is the prototype, tend to crystallize or polymerize intracellularly with consequent distortion of cell shape, reduced cell deformability, hemolysis, and impaired microvascular circulation.

A few abnormal hemoglobin variants exhibit *reduced structural stability*, as evidenced

Table 24-5. Functional Classification of Abnormal Hemoglobins

<i>Functional Abnormality</i>	<i>Location of Substitution</i>	<i>Clinical Abnormality</i>	<i>Example</i>
None	Surface	None	Hb G Philadelphia
Aggregation with reduced solubility	Surface	Hemolytic anemia (homozygous)	Hb S (Chapter 25)
Instability with reduced solubility	Internal nonpolar residues	Hemolytic anemia (heterozygous)	Hb Köln (Table 24-8)
Methemoglobinemia	Proximal (F8) or distal (E7) histidine	Cyanosis	Hb M (Chapter 31)
Increased oxygen affinity	$\alpha_1\beta_2$ Contact or $\beta$ C terminal	Erythrocytosis	Hb Chesapeake (Chapter 30)
Decreased oxygen affinity	Near heme and $\alpha_1\beta_2$ contact	Cyanosis	Hb Kansas (Chapter 31)

by (1) their tendency to precipitate intracellularly, forming inclusion bodies, and (2) their precipitation with mild heating (eg, to 50° C). Most of these unstable hemoglobins result from neutral (uncharged) substitutions affecting internal, nonpolar residues. Many of these substitutions affect residues that contact the heme group<sup>18</sup>; thus, heme-globin bonding is reduced, water may gain access to the heme pocket, and heme may drop out of the molecule. Heme-free normal globin<sup>89</sup> and partially heme-free hemoglobin ( $\alpha_2^{\text{heme}}\beta_2$ )<sup>98</sup> are, themselves, unstable. Some unstable hemoglobins are characterized by a marked change in conformation of the entire molecule, especially those hemoglobins with deletions (eg, Hb Gun Hill), and those in which proline has been inserted into a helical segment, a change which disrupts or bends the helix (eg, Hb Bibba,  $\alpha 136$  (H19) Leu  $\rightarrow$  Pro). The Van der Waals forces upon which structural stability depend are greatly affected by molecular dimensions; therefore, the altered dimensions of the substituted amino acid can have far-reaching consequences. It is likely that the insertion of a changed amino acid into the nonpolar core would result in a completely nonviable molecule<sup>48</sup> unless the charge can be stabilized by internal salt formation, as in Hb Wien, or the charged group can be accommodated on the molecular surface, as in hemoglobins Sogn, Riverdale-Bronx, Shepherds' Bush, and Ann Arbor.<sup>217</sup>

Substitution of a tyrosine for either the proximal (F8: $\alpha 87$ ,  $\beta 92$ ) or distal (E7: $\alpha 58$ ,  $\beta 63$ ) histidine produces an "M" hemoglobin (Chapter 31). These substitutions allow an ionic bond to form between heme iron and the phenolic oxygen of tyrosine, thereby stabilizing iron in the nonfunctional, ferric state. In Hb M Milwaukee ( $\beta 67$  [E11] Val  $\rightarrow$  Glu), a similar ionic bond forms with the glutamic carboxyl group. Such heme groups cannot bind oxygen, and affected patients have methemoglobinemia and cyanosis.

A number of hemoglobins that exhibit increased oxygen affinity, often leading to erythrocytosis, have been described (Table 30-3). Most of the substitutions producing this abnormality occupy an  $\alpha_1\beta_2$  contact

point, where they impair subunit (heme-heme) interaction. A few have been near the C-terminal end of the  $\beta$ -chain, where they interfere with the alkaline Bohr effect, with 2,3 DPG binding, or with the formation of salt bridges that tend to stabilize hemoglobin in the deoxy, low oxygen affinity state (Chapter 4, page 176).

In hemoglobins Kansas, Seattle, and Hammersmith, oxygen affinity is reduced sufficiently to produce cyanosis. A mild reduction in oxygen affinity without cyanosis is found in a few others, such as HbE and certain unstable hemoglobins (page 816). The substitution in Hb Kansas ( $\beta 102$  [G4] Asn  $\rightarrow$  Thr) occurs at a residue which forms part of the  $\alpha_1\beta_2$  contact and which also contacts the heme group. A hydrogen bond normally serving to hold dimers together cannot form; hence this hemoglobin easily splits into dimers. The reduced oxygen affinity of Hb Seattle remains unexplained.

## Laboratory Approach to Abnormal Hemoglobin Identification

### Electrophoresis

Hemoglobin electrophoresis is the single most useful laboratory procedure for the detection and identification of abnormal hemoglobins. This technique separates proteins according to charge; thus, its principal limitation is its inability to detect amino acid substitutions that do not alter charge, such as those found, particularly, in certain of the unstable hemoglobins and the hemoglobins with increased oxygen affinity.<sup>50a,57</sup> It has been calculated that 2200 abnormal hemoglobins can theoretically occur as the result of single amino acid substitutions and that only about one third of these would have an abnormal charge.<sup>48</sup> That most presently known hemoglobins, with the exceptions noted, are electrophoretically abnormal is explained by the fact that electrophoresis was used as the screening method whereby many of them were detected.

Moving boundary electrophoresis in a Tiselius apparatus was the method used by Pauling et al to detect Hb S.<sup>8</sup> Because of the expense and bulk of such apparatus, this method soon was replaced in many laboratories with various techniques for zone electrophoresis, by means of which protein components move as separate zones on various types of supporting media. A wide variety of such methods are available. These differ from one another in the nature of the supporting medium, the buffer, the apparatus, and other methodologic details. Techniques based on filter paper as a supportive medium were the first to be used in routine laboratories<sup>146</sup>; however, because of relatively poor resolution, inability to demonstrate the HbA<sub>2</sub> fraction, and difficulty in quantitation, this method lost favor. Electrophoresis on starch gel rapidly became the method of choice in research laboratories because of its sensitivity and superior definition of zones.<sup>169,199</sup> Most of the available information regarding electrophoretic properties of the hemoglobin variants has been obtained with the starch gel method. Nevertheless, it is too cumbersome and the migration time too long for most routine laboratories. The simplest and most popular routine methods employ cellulose acetate membranes,<sup>144,163,166</sup> for which many types of electrophoresis equipment are available commercially. With this method, hemoglobin electrophoresis can be completed in 30 to 120 minutes. The technique can be made quantitative by elution of zones and spectrophotometric measurement of the hemoglobin that they contain or by spectrophotometric scanning of stained and clarified membranes.

Routine electrophoresis for screening purposes is carried out at alkaline pH (usually 8.6 to 9.1) with tris-EDTA-borate (TEB) buffer or with a "discontinuous" buffer system (TEB in the anodal well and barbital buffer in the cathodal well). Under these conditions, abnormal hemoglobins can be divided into six major groups, depending on their mobility in relation to simultaneously analyzed "marker" hemoglobins—ideally, hemoglobins A, S, and H<sup>169</sup> (Fig. 24-1 and Table 24-6). The six groups are named ac-

Fig 24-1. Electrophoretic mobility of six hemoglobin groups at pH 8.6. The groups are named for the principal hemoglobin with that mobility. For others in each group see Table 24-6.

cording to the principal hemoglobin in the group. With very careful technique and additional "markers," even further differences in mobility may be observed (Fig. 24-2), but such fine distinctions are not possible in most clinical laboratories.

Table 24-6. Electrophoretic Mobility of Certain Hemoglobins<sup>169</sup>

Group*	Mobility	Principal Hemoglobins
C	Slower than S. HbA <sub>2</sub> is a marker	C, E, A <sub>2</sub> , O, F Alexandra
S	Slow. Hb S is a marker	S, D Stanleyville-2 Lepore
G	Slower than A. faster than S	G, L, P, Q
A	HbA is a marker	A M, F†, unstable Hb s, certain Hb s with increased O <sub>2</sub> affinity‡
J	Faster than A, slower than H	J, K, N, Norfolk
H	Very fast. HbH is a marker	H, I Bart's

\*Named for principal hemoglobin in the group  
 †HbF is slightly slower than HbA on starch gel  
 ‡See Tables 24-8 and 30-3

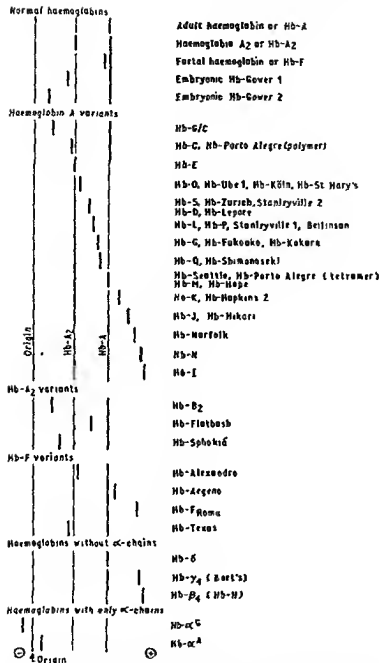

Fig 24-2. Relative electrophoretic mobility of human hemoglobin variants at pH 8.6 on starch gel (From Huehns and Shooter,<sup>199</sup> courtesy of the authors and Journal of Medical Genetics)

Electrophoresis in agar gel at acid pH (usually in citrate buffer, pH 6.2) is a useful procedure for further fractionation of some of the groups described above.<sup>143,165,170</sup> It is not a satisfactory screening technique because it cannot distinguish many abnormal hemoglobins from HbA. However, it can separate

the C group into three fractions: C, O, and E plus A<sub>2</sub>. Also, the method can distinguish Hb S from HbD, HbF from HbA, hemoglobins Little Rock, Ranier and Bethesda from HbA,<sup>21</sup> and HbH from HbL.

The M hemoglobins can be separated from HbA by converting all hemoglobin to meth-

moglobin with ferricyanide, then performing electrophoresis at pH 7.0, usually on starch gel.<sup>151</sup>

## Tests Based on Altered Physical or Chemical Properties

### Tests for Hb S

Hemoglobin S may be detected by the sickling phenomenon and also by methods that measure hemoglobin solubility. These are discussed in Chapter 25 (page 838). In particular, Hemoglobin SD disease can be distinguished from sickle cell anemia by a differential solubility test.<sup>157</sup>

### Tests for Hb F

Hemoglobin F is most easily quantified by means of the alkali denaturation test.<sup>141,147,148</sup> Hb A is denatured by a one-minute exposure to a standardized solution of KOH (pH = 12.7) at room temperature, whereas Hb F resists denaturation under these conditions. The denatured hemoglobin is precipitated with ammonium sulfate and any hemoglobin remaining in the solution is measured spectrophotometrically. The test can measure Hb F in amounts greater than 0.5% with a high degree of accuracy. Hb Bart's and Hb Ranier also resist alkali denaturation.<sup>22</sup>

The cellular distribution of Hb F can be evaluated with a differential staining technique.<sup>160,168</sup> Hemoglobin A is eluted from red cells on a fixed blood film with a citric acid-phosphate buffer (pH 3.2), but Hb F remains in the cells. If, after such treatment, the slides are stained with hematoxylin and erythrosin,<sup>148</sup> cells containing large amounts of Hb F stain darkly, whereas cells with little or no Hb F appear unstained and empty. In most of the hemoglobinopathies and thalassemias, all circulating Hb F is found in a single cell line, thus, two distinct populations will be seen with the described procedure, and the size of the darkly staining population is proportional to the amount of Hb F. The only well-documented exception to this generalization is hereditary persistence of

Hb F (Chapter 26, Fig. 26-10) in which the Hb F is evenly distributed among the erythrocytes.

### Tests for Unstable Hemoglobins

The heat denaturation test<sup>149</sup> has been a useful screening test because many unstable hemoglobins are not detected by routine electrophoretic procedures. Clear hemolysates from the patient and a normal control are incubated with an equal amount of 0.1M phosphate buffer, pH 7.4, at 50° C for one to two hours, and the preparations are examined at intervals for precipitation. Alternatively, somewhat higher temperatures (60° to 65° C) may be used for shorter periods.<sup>31,40</sup> Normal hemoglobin remains in solution much longer under these conditions than the unstable hemoglobins (Table 24-8). Usually, an abnormal result is apparent on visual inspection of the amount of precipitate in the tube. The quantity precipitated can be measured by analyzing the supernatant solution for hemoglobin before and after a two-hour incubation at 50° C and calculating the difference. The rate of precipitation can be more precisely estimated by removing aliquots at five-minute intervals during a 60° or 65° C incubation and analyzing as described above. A graph constructed from such data demonstrates dramatic differences between a normal hemolysate and one containing an unstable hemoglobin (Fig. 24-3).

Another promising method for detecting unstable hemoglobins is the isopropanol precipitation test of Carrell and Kay.<sup>145</sup> In this test, 0.2 ml of a freshly prepared hemolysate is added to 2.0 ml of a 17% (by volume) solution of isopropanol in 0.1M Tris-HCl buffer, pH 7.4, and incubated at 37° C. With hemolysates from seven different unstable hemoglobins (Christchurch, Sydney, Köln, Wien, Niteroi, Shepherds' Busb,<sup>145</sup> and Southampton<sup>42</sup>), unequivocal clouding was observed at five minutes and a flocculent precipitate had formed within 20 minutes. With 200 hemolysates from normal subjects, no precipitation was observed until after 40 minutes. With hemolysates containing Hb H, a slight opacity was observed at 10 minutes.

Fig 24-3. The heat denaturation test in a patient with Hb Istanbul (propositus) as compared with control. The test was performed at 60°C (From Aksoy et al<sup>23</sup> courtesy of the authors and *Journal of Clinical Investigation*.)

Precipitated material can be used for further chemical analysis.

Inclusion bodies may sometimes be demonstrated with supravital dyes (eg, methyl or crystal violet) in red cells containing unstable hemoglobins (page 813). These so-called Heinz bodies are not specific for unstable

hemoglobin disease, since they also may appear in glucose 6-phosphate dehydrogenase deficiency and related disorders (Fig. 24-4). Furthermore, the inclusions usually are not detected in patients with unstable hemoglobin disease unless the spleen has been removed. Various measures induce the appearance of such inclusions in nonsplenectomized patients, such as 24- or 48-hour incubation at room temperature<sup>149</sup> or the addition of sodium nitrate<sup>148</sup> or acetylphenylhydrazine.<sup>142</sup> In general, however, the test is less specific and less sensitive than the heat or isopropanol denaturation tests. Prolonged incubation with brilliant cresyl blue is a useful procedure for distinguishing Hb H from Hb I because only Hb H forms inclusions. The Hb H inclusions appear as fine, dust-like particles rather than the larger Heinz bodies.<sup>164</sup>

### Chromatography

Separation of hemoglobins on chromatographic columns has been accomplished with

Fig 24-4. Heinz-body formation in blood of persons sensitive to primaquine (B) compared with that in nonsensitive individuals (A). The red corpuscles were incubated with 1.0 g/l acetylphenylhydrazine solution for four hours. Wet preparations stained with crystal violet (Magnification, 1300×) (From Beutler et al,<sup>142</sup> courtesy of the authors and *Journal of Laboratory and Clinical Medicine*.)

various ion-exchange resins, including diethylaminoethyl (DEAE) cellulose,<sup>153</sup> DEAE Sephadex,<sup>154</sup> carboxymethyl (CM) cellulose,<sup>156</sup> CM Sephadex,<sup>150</sup> and Amberlite IRC-50<sup>155</sup> (see Fig. 4-15, page 173). Although mainly suited for research purposes, particularly for purification of hemoglobins prior to chemical analysis, chromatographic techniques also have been adapted for use as a diagnostic method in some laboratories.<sup>169</sup> For example, they can serve as an alternative to acid-agar gel electrophoresis for such purposes as separating Hb A from Hb F, Hb H from Hb I, and C from O and E. A chromatographic method may also be used to separate and quantitate Hb A<sub>2</sub> in the presence of Hb C.<sup>94</sup>

### Hybridization

Hybridization is used to determine which of the polypeptide chains in an abnormal hemoglobin contains the substituted amino acid. The  $\alpha$ - and  $\beta$ -chains are dissociated at low pH and recombined with similarly dissociated chains of canine hemoglobin. The products are analyzed by starch gel electrophoresis. Four hemoglobins will be found—human, canine, and two hybrids formed from the  $\alpha$ -chains of one species and the  $\beta$ -chains of the other. The abnormal chain can be identified by the altered position of the hybrid containing it.<sup>152</sup>

### Peptide Analysis

The first step in defining the precise abnormality in an abnormal hemoglobin consists of breaking the molecule down into smaller peptides. Usually this is accomplished by proteolysis with trypsin, a procedure that cleaves the protein at lysyl and arginyl residues, thereby forming 14 peptides from the normal  $\alpha$ -chain and 15 from the  $\beta$ -chain. Some of these peptides remain insoluble (the "core"), unless trypsin hydrolysis is preceded by S-aminoethylation, which allows trypsin cleavage also to occur at cysteine residues.<sup>158</sup>

The tryptic peptides are then separated from one another. Most frequently, this has

been accomplished by applying the mixture to filter paper and performing high-voltage electrophoresis along one axis and chromatography along the other. Each peptide then occupies a unique position on the filter paper, and the resulting pattern, stained with ninhydrin, is called a "fingerprint" or peptide map<sup>6</sup> (Fig. 24-5). The peptide containing the abnormal amino acid is identified by its changed position. Alternatively the peptides can be separated by automatic column chromatography procedures, the abnormal peptide being characterized by an altered elution volume<sup>158</sup> (Fig. 24-6).

Individual peptides may be eluted from the "fingerprint" or collected from the column and subjected to chemical analysis to determine the amino acid sequence, usually by the Edman degradation methods.<sup>162,167</sup>

Peptide analysis and amino acid sequencing are techniques suited only to a well-equipped research laboratory. They are used only when precise identification is required and especially when a possible new variant is detected. Nevertheless, at least one abnormal hemoglobin could not be detected by any means other than peptide analysis.<sup>57</sup>

### Prevalence<sup>202</sup>

The frequency of the abnormal hemoglobins varies considerably with geographic location and racial group. Four hemoglobins, S, C, D Punjab, and E, often are called the "common hemoglobins" because each affects millions of individuals.

Hemoglobin S is certainly the most common of all abnormal hemoglobins. It is found particularly in equatorial Africa in a broad zone extending from coast to coast<sup>202</sup> (Fig. 24-7). The highest incidence occurs in the eastern part of the continent, where 40 to 50% of the members of certain tribes are affected. A prevalence rate of 10 to 20% is common throughout other parts of the zone, but there is considerable variation from one tribe to another.<sup>201</sup> For example, only 2.9% of members of the Hamitic tribes carry the gene as compared with 19% of Bantus. Hemoglobin S also is found in Southern

Fig. 24-5. Peptide map ("fingerprint") of tryptic digests of an equal mixture of Hb G San Jose and Hb S (left) compared with that of Hb A (right). The peptide from Hb A (indicated by the arrow) is absent from the pattern of G and S and is replaced by two abnormal peptides (indicated by arrows, one from G and the other from S) (Prepared by Dr. Robert L. Hill)

Turkey, Arabia, and India, predominantly in relatively isolated and primitive people.<sup>200</sup> It was suggested that the African and Indian populations inherited the gene independently from a common source in the Middle East. From this source, the gene may have been introduced into Africa via a land bridge that once connected the continents, and from there spread westward. Sickle cell trait also occurs in areas along the Northern Mediterranean shores (Fig. 24-7), especially in Greece where as many as 32% of the inhabit-

ants of certain villages exhibit the sickling phenomenon.<sup>195</sup>

The incidence of the sickle cell gene in migrant Negro populations probably reflects the African origin of these people. In the USA, the overall prevalence of the trait among Negroes is about 8% (Table 24-7), but there may be considerable variation in different parts of the country. A lower incidence is found in the north, possibly because of greater racial admixture, whereas in such isolated populations as the Gulla Negroes of

The solid line indicated absorbance at 570 nm of the ninhydrin reaction products of peptides. Each zone, numbered with Roman numerals, represents a single peptide. The shaded zone IV is the abnormal peptide; the pattern is otherwise identical to that of the normal  $\beta$ -chain. The pH of the effluent is shown as a dashed line. (From Jones et al.,<sup>139</sup> courtesy of the authors and Science)

Fig 24-7 Geographic distribution of sickling trait  $\beta$ - and  $\alpha$ -thalassaemia, hemoglobins C and E and Hb-D $\beta$ -Punjab. In Western Africa Hb-C is found in addition to Hb-S, as indicated in the map (Specially prepared by Dr Hermann Lehmann)

South Carolina, the prevalence of Hb S approaches 20%.<sup>202</sup> The frequency of the gene in Central and South America and in the West Indies is similar to that in North America. Additional prevalence rates in various countries have been assembled by the World Health Organization<sup>209</sup> and by Livingstone.<sup>202</sup>

Compared with Hb S, Hb C is found in a much smaller and more sharply demarcated geographic zone in Western Africa (Fig. 24-7). The greatest prevalence is in Northern Ghana, where 28% of the population harbor the gene.<sup>196</sup> The frequency declines sharply to the south, east, and west. Within Nigeria, the River Niger seems to have acted as a barrier to eastward spread. In the USA, about 3% of the Negro population carries the Hb C gene (Table 24-7).

Hemoglobin E is most prevalent in South-

east Asia,<sup>202</sup> affecting over 50% of the population in eastern Thailand (Surin Province) and from 20 to 45% in other parts of Thailand and in Cambodia, Laos, and Burma. A somewhat lower prevalence, 3 to 8%, is found in Vietnam. From the mainland, the gene spread southward to parts of Indonesia, but the incidence is low in India to the west and in China to the northeast.

Hemoglobin D Punjab is found in the greatest frequency (2%) among the Sikhs of the Punjab in India (Fig. 24-7) as well as in nearby Gujarat (1%)<sup>193</sup> and in Iran. It has also been found in American Negroes (0.4% in North Carolina<sup>194</sup>) sporadically in Caucasians throughout the world, and in American Indians.<sup>193</sup>

The high prevalence rates of the "common" hemoglobins as well as thalassemia (Chapter 26) and G6PD deficiency (Chapter

23) suggest that the deleterious effects of the homozygous states of these disorders are counterbalanced by the selective advantage that they provide to heterozygous individuals ("balanced polymorphism").<sup>206</sup> By this mechanism, the gene frequency increases in the population despite the adverse effects on survival of homozygous individuals, because the heterozygote is "fitter" in the genetic sense than a normal subject. Most of the studies of this phenomenon have dealt with the role of malaria, especially *falciparum* malaria, as the selecting agent and with the possible resistance to malaria offered by subjects heterozygous for the above disorders.

The "malaria hypothesis" is best established with respect to hemoglobin S. The geographic distributions of *falciparum* malaria and Hb S coincide remarkably,<sup>199</sup> and the frequency of sickle trait is correlated with the endemicity of malaria in many tribes.<sup>192</sup> Furthermore, a lower rate of parasitization of the blood is found in subjects with sickle

trait<sup>191,207</sup> even when they are deliberately inoculated with the parasite,<sup>192</sup> and the mortality rate from cerebral malaria is much lower in children with the trait than in those free of Hb S.<sup>204,207</sup> The mechanism of malarial resistance has not been established, but the most likely hypothesis is that the invaded cells adhere to vessel walls where they become deoxygenated and assume the sickled shape, which in turn leads to their destruction by phagocytosis.<sup>203</sup> When red cells are used in in vitro culture systems, growth occurs as well in Hb S cells as in normal cells.<sup>207</sup>

Most other hemoglobin variants are rare.<sup>202</sup> Many have been reported in a single individual or in a single family. Occasionally, in isolated populations, a minor variant may attain considerable prevalence; for example, Hb J Tongariki was found to affect nearly 10% of the population on an island in the Pacific.<sup>197</sup> In a survey of 8000 Europeans (5000 Danish, 3000 British), 11 persons with electrophoretically identifiable abnormal hemoglobins were detected.<sup>208</sup> Since only about one third of hemoglobin variants would be detected by this technique (page 805), and also allowing for the fact that certain substitutions are "forbidden" since they would produce a nonviable molecule, it may be calculated that the overall prevalence of abnormal hemoglobins in Europeans may be about 0.5%.<sup>48</sup>

## Unstable Hemoglobin Disease<sup>221,247</sup>

### (Congenital Heinz-Body Hemolytic Anemia)

In 1890, Heinz described the staining characteristics of the red cell inclusions that now bear his name.<sup>230</sup> For the next 60 years, Heinz bodies were considered to be solely a manifestation of exposure to various kinds of toxins.<sup>246</sup> Their relation to primaquine-induced hemolytic anemia, in particular, was established in the 1950's (Chapter 23). In 1952, Cathie reported a patient in whom similar inclusions were found in the absence of toxic exposure.<sup>224</sup> In this patient, a sple-

nectomy had been performed because of severe, congenital hemolytic anemia. This congenital form of Heinz-body anemia was more fully delineated by Lange and Akeroyd<sup>236</sup> and by Schmid et al.<sup>212</sup> who reported cases similar to Cathie's and observed the association with the urinary excretion of a brown, dipyrrolic pigment. Schmid's patients, being father and son, provided evidence that the disease was familial.

The first suggestion that an abnormal hemoglobin might be implicated in pathogenesis was made by Scott and coworkers, who found an electrophoretically abnormal hemoglobin component in a patient with congenital Heinz-body hemolytic anemia.<sup>213</sup> Their suggestion was supported by the discovery that Hb Zurich was associated with an inclusion-body hemolytic anemia, although only after exposure to sulfonamides.<sup>228</sup> That an abnormal hemoglobin might be present but electrophoretically "silent" was proposed by Dacie et al, who found a heat-labile hemoglobin fraction in their patients.<sup>149</sup> The discovery of Hb Köln and the determination of its molecular abnormality constituted final proof that congenital Heinz-body hemolytic anemia was a hemoglobinopathy.<sup>222</sup> Other unstable hemoglobins—Genova,<sup>53</sup> Sydney,<sup>223</sup> and Hammersmith<sup>225</sup>—were soon found to produce a similar picture. Now, over 40 unstable variants have been identified (Table 24-8), and a clearer picture of the spectrum of disease that they produce has emerged.

### Incidence

Despite the large number of reported variants (Table 24-8), unstable hemoglobin disease is considered to be rare. Most of the reports deal with single cases or single kindreds. A few unstable hemoglobins have occurred in two or a few unrelated families.<sup>224a</sup> *Hemoglobin Köln disease* is much more common than the others, however. At least 43 patients with this hemoglobin, in 11 apparently unrelated families, have been described.<sup>50b,149,222,226,227,229,231,232,237,238,240,245</sup>

pressed in heterozygous individuals; thus, the inheritance pattern is autosomal dominant. Homozygous disease has not been reported and would likely be lethal. In at least 14 instances,<sup>239</sup> both parents of an affected individual were normal, indicating that a spontaneous mutation had occurred. This type of pedigree was particularly common with the variants producing severe or moderately severe disease, possibly because patients with severe disease are less likely to reproduce.

### Clinical Manifestations and Degree of Anemia

Unstable hemoglobin disease varies considerably in severity. A classification has been

proposed<sup>235</sup> in which the reported variants are divided into four groups according to the intensity of the associated hemolytic process and the response to splenectomy (Table 24-8). With seven variants, the disease was considered *severe*. Hemolytic anemia usually became apparent in infancy, and the blood hemoglobin level ranged from less than 4 to about 8 g/dl. The reticulocyte count was reported to be very high, often 50% or more, but such values may be falsely high.<sup>235,247</sup> Splenectomy, followed by no clinical improvement, had been performed in all but one<sup>42</sup> of these patients.

In a second group of 10 variants, disease was *moderate* in severity. The disorder often was not detected until late in childhood or during adolescence. Often, symptoms of cholelithiasis, episodic jaundice, splenomegaly, or a hemolytic crisis were the presenting manifestations. Prior to splenectomy, the blood Hb averaged about 9 g/dl (range 6 to 11 g/dl) with 4 to 20% reticulocytes. After splenectomy, anemia was mild or absent, but reticulocytosis persisted.

*Mild* hemolytic disease has been associated with the majority of unstable variants. In the steady state, anemia was absent or mild, but the reticulocyte count often ranged from 4 to 10%. Splenomegaly was not a usual finding in this group. Many of the patients were detected because of a "crisis" characterized by an abrupt increase in the degree of anemia. Crises in either mild or moderate disease appeared to be precipitated by episodes of infection; less often, by ingestion of certain drugs. Drug-induced hemolytic anemia was best documented in the patients with hemoglobins Zürich,<sup>228</sup> Torino,<sup>239</sup> Peterborough,<sup>45</sup> and Shepherds' Bush,<sup>63</sup> and the offending agents were sulfonamides. Whether drug sensitivity is a feature of the other unstable hemoglobins is less clear. Administration of a sulfonamide did not shorten survival of erythrocytes containing Hb Sogn.<sup>50</sup>

Patients with Hb Köln disease usually have mild manifestations; however, this varies from one kindred to the next and even among different individuals in the same kindred.<sup>221</sup> Occasionally, moderately severe anemia has

been observed. Splenectomy usually was considered unnecessary, but, when performed, improvement generally occurred.

Hb Seattle was classified with the mild diseases even though the blood Hb level was about 10 g/dl. Signs of hemolysis were lacking (reticulocytes, 3%), and it was suggested that the low oxygen affinity of this variant made tissue oxygenation more efficient; thus, the red cell mass was "appropriately" decreased and erythropoiesis was not stimulated.<sup>244</sup>

A fourth group of hemoglobins are unstable *in vitro*, but are not associated with signs of hemolytic anemia on routine testing (Table 24-8).

Patients in any of the first three groups may complain of *dark urine*, varying from brown to almost black in color. In general, the degree of discoloration is related to the intensity of hemolysis. However, the patient may experience episodes of dark urine intermittently without clear relation to other signs of hemolysis. One review indicated that pigmenturia was found in 33 of 36 patients in whom search for it was made.<sup>227</sup> However, with some hemoglobins (eg, Philly, Riverdale-Bronx, Sydney, Sabine) no pigmenturia has been observed (see page 817). The pigment is thought to be a dipyrrole related to the mesobilifuscin group (Chapter 5) and to be derived from the degradation of the heme released when Heinz bodies form *in vivo*. Similar or identical pigments may occur in thalassemia (page 866).

### Laboratory Findings

The degrees of anemia and reticulocytosis and the occurrence of pigmenturia have been discussed above. The MCHC is reduced in many instances, sometimes to as low as 25 g/dl RBC. Presumably this occurs because the unstable molecule is partially heme deficient, because hemoglobin is lost from the cells with splenic removal of inclusions, or because the hemoglobin in Heinz bodies is not measured by hemoglobinometry. Microscopic examination of the blood usually reveals only nonspecific signs of hemolysis:

polychromatophilia, stippling, and anisopoikilocytosis; hypochromia may also be found. With severe disease, fragmented cells and microspherocytes may be observed. Moderate thrombocytopenia has been detected in a few patients, possibly because of splenic sequestration.<sup>231</sup>

*Inclusion bodies* (Heinz bodies) usually are found only after splenectomy or during an acute hemolytic episode. Under such circumstances, more than 50% of the cells typically contain one large, spherical inclusion when stained with methyl violet or brilliant cresyl blue. Schmid emphasized that these inclusions differ from the classic Heinz bodies seen with toxic exposures in that they are larger, are found in reticulocytes rather than older cells, and may be faintly visualized on Wright's stain.<sup>242</sup> When not present in fresh blood, inclusions may be induced to form *in vitro* by various techniques (page 809). The inclusions consist mainly of denatured globin, although various other cellular constituents, including porphyrins and nucleic acids, may be nonspecifically adsorbed. Usually, the precipitated globin lacks heme, but with some variants (eg, Hb Philly) the heme remains with the globin.

*Hemoglobin electrophoresis* may or may not detect the abnormality. Hemoglobin Köln migrates more slowly than Hb A when routine methods are used. Other variants may migrate slower or faster than Hb A, or may be inseparable from it. In a number of instances, an inhomogeneous streak trailing behind Hb A has been described, presumably the result of denaturation or heme loss occurring during electrophoresis. In such circumstances, a more discrete band may be seen if electrophoresis is performed at 10° C.<sup>227</sup> Electrophoretic behavior cannot be predicted from the change in charge induced by the amino acid substitution; the altered tertiary structure exposes some groups normally hidden and conceals others, thereby changing the overall surface charge. With  $\beta$ -chain unstable hemoglobins, free  $\alpha$ -chains may be found on electrophoresis; these typically have even slower anodal mobility than Hb A<sub>2</sub>.<sup>247</sup> In addition, heme-depleted unstable hemoglobin

( $\alpha\beta^{\text{heme}}\beta_2^*$ ) may be found, usually migrating just in front of Hb A<sub>2</sub>. Hb A<sub>2</sub> levels may be increased to as much as 5% in association with unstable  $\beta$ -chain variants, and Hb F levels may be increased to as much as 10 to 12%.

Certain abnormalities may be detected with *in vitro* hemolytic testing, but the findings are not specific. *Autohemolysis* is increased in a majority of patients<sup>227,247</sup> to values of about 5 to 6% in mild or moderate disease and as high as 15 to 25% in severe disease. There is partial correction with glucose and ATP; ie, a "Type I" pattern (page 735). Erythrocyte osmotic fragility may be normal, increased, or decreased.<sup>227</sup>

Various studies of *glycolysis* and the hexose-monophosphate shunt in erythrocytes have disclosed normal or increased overall rates, generally consistent with the immaturity of the cell population. Erythrocyte glutathione (GSH) levels may be high, normal, or low. When low levels are found, they probably result from binding of GSH by the unstable variant. GSH can form mixed disulfides with the normally reactive  $\beta 93$  cysteine and, as denaturation proceeds, with the normally unreactive  $\alpha 104$  and  $\beta 112$  cysteines.<sup>234</sup> Glutathione stability usually is normal, but may be slightly reduced.<sup>227,247</sup>

Erythrocyte survival often is shortened. Values for  $t_{1/2}$  Cr have varied from 2 days in severe disease, and 6 to 16 days in moderate disease, to 9 to 23 days in mild disease.<sup>235</sup> There is poor correlation, however, between the blood Hb level and  $t_{1/2}$  Cr,<sup>247</sup> and several factors may make the results misleading. For example, chromium binding and elution rates probably are abnormal in unstable hemoglobins.<sup>217</sup> DF<sup>32</sup>P studies probably would be more reliable, but have not been reported.

Because the nature of the amino acid substitution often affects heme function, the *oxygen affinity* of unstable hemoglobins may be disturbed. Oxygen affinity is *increased* (ie,  $P_{50}$  is decreased, page 107) in hemoglobins Köln, Shepherds' Bush, Casper, St. Etienne, Zurich, Freiburg, and Gun Hill. Oxygen affinity is *decreased* ( $P_{50}$  increased) with hemoglobins Torino, Leiden, Peterborough,

Seattle, Hammersmith, Bristol, and Louisville. In some instances, *methemoglobin* levels have been increased to about 5% in fresh blood.<sup>247</sup> More often, excessive methemoglobin (20 to 30%) has been found after sterile incubation at 37° C for 24 to 48 hrs.

## Diagnosis

At present the most reliable test for unstable hemoglobin disease is the heat denaturation test (page 808). This has been positive in all reported instances except for the patient with Hb Bryn Mawr, in whom the abnormal variant constituted only 2% of the hemoglobin.<sup>29</sup> With the quantitative heat denaturation procedure, 8 to 45% of the hemoglobin precipitates as compared with less than 1 to 2% in the normal. In Hb Köln disease, about 10 to 15% precipitates. With some variants, modifications of time and temperature have been required in order to demonstrate the heat lability.<sup>34</sup> Other tests for instability, including the isopropanol precipitation test (page 808) and precipitation with p-chloromercuribenzoate,<sup>234a,241</sup> may be equally reliable, but less information is available concerning them.

Precise identification of the abnormal hemoglobin requires peptide analysis (page 810), which is performed in only a few research laboratories throughout the world. However, for the clinical hematologist, exact knowledge of the substitution may not be necessary, since management does not depend upon it.

## Pathogenesis

The nature of the molecular lesions leading to hemoglobin instability were discussed on page 804. As a result of most of these lesions, water gains entrance to the heme crevice, making the heme iron susceptible to oxidation, and loosening the heme-globin linkage. When heme is lost, globin solubility is markedly reduced and usually unreactive cysteine sulfhydryl groups are exposed and form disulfide linkages with GSH and membrane sulfhydryl groups.<sup>234</sup> The heme-free

$\beta$ -chains precipitate, forming inclusion bodies, and the liberated heme is catabolized to dark-brown dipyrroles, which are excreted into the urine. Free  $\alpha$ -chains are left behind and may be detected during electrophoresis. With some variants (eg, Hb Philly and Hb Christchurch<sup>248</sup>) the heme probably remains with the globin after precipitation, and dipyrroluria does not occur. Formation of inclusions and their binding to membranes lead to loss of membrane sulfhydryl groups and increased cation permeability. Hemolysis occurs chiefly because cells containing inclusions are sequestered in the RE system, where either the inclusions are removed or the cells are destroyed, depending on the degree of damage.

## Treatment and Prognosis

Splenectomy may bring about some improvement in moderately affected patients.<sup>235</sup> Unfortunately, those with the most severe disease do not respond to the operation (Table 24-8), presumably because the more severely damaged erythrocytes are destroyed in the liver and other parts of the RE system as readily as in the spleen.<sup>247</sup> When splenectomy is to be performed, it is desirable to delay the operation until the patient is four years old or older, since the risk of infection appears to be increased in splenectomized younger children (Chapter 8).

Patients who are not candidates for splenectomy should be managed with the general measures recommended for hemolytic anemia (Chapter 20). Blood transfusions should be held to a minimum and usually reserved for a severe crisis. Sulfonamides and other drugs with a redox potential (Table 23-2, page 785) should probably be avoided, although, as already mentioned, their deleterious effects have been documented in only a few instances. Intercurrent infections should be detected and treatment instituted promptly. If there is reason to believe that the diet is inadequate, low doses of folic acid (0.15 to 0.3 mg per day) may be used prophylactically (Chapter 14).

The long-term prognosis remains un-

known in this relatively recently described illness. Only one death has been reported, probably from overwhelming sepsis in a splenectomized patient with Hb Hammer-smith.<sup>247</sup>

### Introduction

In this chapter, sickle cell trait and sickle cell anemia as well as the more common hemoglobinopathies such as HbC, HbD, and HbE, as well as HbO, and their combinations with HbS will be considered. In Chapter 26, hemoglobinopathies associated with thalassemia are discussed.

All of the abnormal hemoglobins are in-

herited defects (Chapter 24). The spontaneous appearance of such mutations is exceedingly rare. Among patients who bear the hemoglobins to be described in this chapter the *heterozygote* rarely manifests any clinically significant phenotypic expression. In this sense these hemoglobinopathies are recessive traits. However, most heterozygotes are easily detected by simple laboratory tests. In that respect they are not phenotypically silent.

On the other hand, disease, often quite serious, is the usual consequence of the *inheritance of two genes* for these abnormal hemoglobins. This is true when the two genes are for the same abnormal hemoglobin, as in sickle cell anemia, or when two different genes are inherited, as in sickle cell-hemoglobin C disease.

### Terminology

A word about terminology will be helpful. When a person is found to have inherited one abnormal gene he is referred to as having the *trait* for that abnormality. If he has inherited two abnormal genes the disorder is referred to in several ways. The illness in persons who have inherited two HbS genes is called sickle cell anemia. In those who have inherited two different abnormal hemoglobins the designation incorporates the names of both, eg,

HbSC disease, HbS-thalassemia. Because its meaning is less clear than "sickle cell anemia," the term HbS disease is best avoided. The designation *HbS* or *sickle cell diseases* (SCD) is used, however, in a generic sense to refer to all the conditions in which the gene for HbS is associated with another abnormal hemoglobin gene, with accompanying clinical manifestations.

## Sickle Cell Trait and Sickle Cell Anemia

### Incidence and Geographic Distribution

As indicated in the preceding chapter, hemoglobin S is the result of the substitution of valine for glutamic acid at the sixth residue of the  $\beta$ -polypeptide chain of hemoglobin. The gene for HbS occurs with varying frequency in sub-Saharan Africa, the Mediterranean countries, and India and in the descendants of people who emigrated from these regions, namely, Negroes in South, Central, and North America. When inherited from only one parent, as mentioned above, HbS causes ill effects only under special circumstances (HbAS, sickle cell trait, page 839). Inherited from both parents, a chronic, severe hemolytic anemia (sickle cell anemia [SCA]) results.

There is much yet to be learned about the natural history of SCA. The symptoms vary considerably in severity from one patient to another, but they are essentially those attributable to the chronic severe anemia and to vascular occlusive episodes. The disorder is distinguished by the presence of peculiar poikilocytes that are commonly sickle or oat shaped. SCA has also been referred to as drepanocytic anemia and as meniscocytosis.<sup>62</sup>

Contrary to commonly held opinion, there is a high incidence of sickle cell anemia in tropical Africa. It has long been known as a symptomatic entity to health-care teams in the countries of this region.<sup>174</sup> Affected persons in Africa have at times been identified by limb-girdle tattoos and the disorder has been given onomatopoeic names denoting the character of the recurrent, unrelenting, pain-

ful, vaso-occlusive crises that the patient experiences.<sup>174</sup>

The HbS gene in Africa is geographically distributed in a broad, equatorial belt limited on the north by the Sahara Desert and the Ethiopian Highlands, on the south by two rivers, the Kunene and the Zambesi.<sup>230</sup> (Fig. 24-7, page 812.) Its relation to the endemicity of malaria was discussed earlier (page 813). The incidence of the sickle cell gene ranges from 0 in some mid-African tribes to 40% in others.<sup>192,354</sup> HbS is found in lesser frequencies in other parts of Africa. The average frequency in tropical Africa of HbS is 20%, and if one assumes that persons with SCA rarely reproduce, then an average frequency of SCA at birth would be about 10 per 1000 births. Considerable variation is found, however, within geographically adjacent regions. Thus, in Ghana a sickle trait incidence of 10% was found in the north and 20% in the south.<sup>174</sup>

In the Americas the gene frequency in Negroes is more uniform than in Africa because of the loss of African tribal identities and because the average American Negro has about 20% Caucasian ancestry.<sup>261</sup> Although the reported HbS gene frequency among Negroes in Latin America and the Caribbean varies, an approximation of 8% seems appropriate.<sup>230</sup> In the United States Negro the most likely frequency of the sickle cell trait also is 8% (see Table 24-7, page 813). The expected incidence of SCA at birth would be 1.6/1000 (one in 625). Without correction for mortality the expected number of cases of SCA among the approximately 20 million Negroes in the United States would be about 32,000. Because of the death rate, it has been estimated that the actual number is about one half to two thirds of this figure.

There is a substantial incidence of simultaneous heterozygosity for the HbS gene and one of the genes responsible for thalassemia or one of the other hemoglobinopathies such as HbC, HbD, or HbE. In Ghana the 10 to 20% incidence of HbC trait and the 10 to 20% incidence of HbS trait mean that about 1% of the children have HbSC disease.<sup>174</sup> Thus, in Ghana alone, with a population of

8 million, 30,000 of each million newborns will have either HbSS, HbSC, or HbCC disease.

If one considers HbSC disease and HbS-beta-thalassemia together in the Negro population of the United States, there should be almost as many or even more newborns with these disorders than with sickle cell anemia alone (36,000).<sup>221</sup> (Table 24-7, page 813.) Since the mortality rate of these two disorders is less than that of SCA, their incidence in the population should exceed that of SCA. Similar estimates of the frequency of HbSC disease and possibly of HbS-thalassemia in Central and South America are probably warranted.

### Pathogenesis: Molecular and Cellular Pathology

#### The Sickling Phenomenon

Early studies demonstrated that the erythrocytes from patients with sickle cell disease (SCD) assume the sickle shape when the hemoglobin that they contain is deprived of oxygen.<sup>93,117,121,126</sup> In addition, sickling was shown to be favored by a lowering of pH<sup>303,325</sup> and by increasing the temperature to that of the body. The first visible cellular change, usually detectable within 10 seconds after deoxygenation, is loss of the red cell flicker phenomenon, a periodic movement within the red cells visible by phase microscopy. Simultaneously, or shortly thereafter, a mass of hemoglobin appears to flow to one side of the cell. The cell becomes ovoid, elongated, and crescent-shaped, and ribs of solidified hemoglobin extend from the hemoglobin mass to join a rim of hemoglobin at the opposite perimeter of the cell (Fig. 25-1).<sup>122,236,251</sup> Prolonged deoxygenation results in increased deformation of the cell, and long, thin filaments extend from the body of the cell. These filaments are easily broken off when the sickled cell is manipulated.<sup>154,158</sup>

Reversion to a normal disc shape (unsickling) occurs upon oxygenation of the cell. The changes probably begin within 10 seconds after oxygen reaches the cell and first

become apparent in the projecting filaments. The liquefied hemoglobin may flow from these spicules toward the body of the cell or may become trapped and form a membrane-enclosed hemoglobin bead. Such beads may become detached from the cell during the unsickling process. As the intracellular hemoglobin liquefies, it tends to flow first along the internal rim of the cell and finally into the central portion. At that time the red cell flicker phenomenon reappears.<sup>236</sup>

After being repeatedly subjected to sickling and unsickling, the cell may lose the ability to revert to the normal biconcave discoid shape.<sup>304</sup> Such "irreversibly sickled cells" (ISC's) probably result from the loss of portions of membrane as the microfilaments are shed.<sup>236</sup> Repeated sickling may also cause the formation of inclusions with the morphologic characteristics of small Heinz bodies. These inclusions become attached to the membrane and are partially responsible for premature destruction of the cell.<sup>183,209,284</sup>

#### Molecular Mechanisms

An abundance of information indicates that the alterations in the shape of cells containing HbS are the result of hemoglobin polymerization.<sup>126,245</sup> Cell-free solutions of HbS undergo a pronounced decrease in solubility and an increase in viscosity when deoxygenated.<sup>8,29,30,37,125</sup> If the concentration of HbS in such solutions or in the red cell approaches 30 g/dl, a semisolid gel forms, and the gel contains small, rigid, boat-shaped objects that polarize light. These objects are oematic liquid crystals known as tactoids.<sup>31,126,259,305</sup>

By electron microscopy the polymers of HbS are found to be long, rod-like structures. Each rod is formed from six monomolecular strands of hemoglobin S twisted into a spiral. Tactoids are formed from organization of the rods into bundles. Within the sickled cell these linear polymers lie parallel to the long axis of the cell or projecting filaments.<sup>80,135,186,259,321,343,349</sup>

Although the nature of the molecular interactions producing polymerization is not completely understood, it may be assumed

Fig 25-1. Photographs of a single cell, suspended in plasma (1), which on deoxygenation became ovoid (2) then sickled with spicules and spikes (3), which on oxygenation retracted towards the body of the cell (4-5). The long spicules became pinched at the cell junction (6) and hemoglobin enclosed in membrane formed a fragment which separated (7). A second deoxygenation produced the changes seen in (8) and (9) and reoxygenation (10) ultimately resulted in the permanently irregular "lumpy-bumpy" cell (acanthocyte) shown in (11). All of the protrusions or knobs are permanent deformities, and are located where spikes or spicules were formed during the deoxygenation of the cell.

that the substitution of valine for glutamic acid at  $\beta^6$  creates a site which, when the molecule is deoxygenated, is capable of forming a bond with a normal site on an adjacent molecule.<sup>58,223,224,247</sup> The complementary site is present even on normal or non-HbS abnormal hemoglobin molecules,

whether they be in the oxy- or deoxygenated state.

The observations that decreased temperature, high oxygen pressures, and the carbamylation of the N-terminals of HbS inhibit gelation support the hypothesis that hydrophobic intramolecular bonds form between

the  $\beta$ -N-terminal valine and the abnormal valine at  $\beta^6$  to form a ring. It has been suggested that formation of the ring creates this abnormal site that is involved in polymer formation.<sup>221</sup> However, the observation that salt-depleted hemoglobin solutions gel at lower concentration than do salt-replete solutions suggests that electrostatic bonds also participate in the polymerization.

In forming polymers, HbS reacts to a variable extent with other hemoglobins. In the test tube, a deoxy-HbS molecule copolymerizes most effectively with another HbS molecule, and, in decreasing order, with hemoglobins C, D, E, A, J, and F.<sup>6,24,30,54,708</sup> These observations correlate with the severity of the clinical manifestations of disorders in persons in whom various combinations of these hemoglobins are found. Thus, patients with sickle cell anemia, whose cells contain more than 90% HbS, have the most serious disease, followed by those with sickle cell-HbC disease. In contrast, individuals doubly heterozygous for HbS and hereditary persistence of HbF, whose cells contain about 70% HbS and 30% HbF, rarely if ever have clinical disease.<sup>39,68,218,200</sup>

Two other sites on the hemoglobin molecule have been implicated in the interaction because of the effects of substitution at these sites. In Hb Memphis, the substitution  $\alpha 23$  (B4) Glu  $\rightarrow$  Gln inhibits copolymerization with HbS, suggesting the importance of sites on the  $\alpha$ -chain.<sup>132,179</sup> On the other hand, the substitution of  $\beta 73$  (E17) Asp  $\rightarrow$  Asn in HbC Harlem and HbS Korle Bu also inhibits polymerization.<sup>37,38,176</sup>

### Mechanisms of Hemolysis

It has been estimated that about one third of the total cell destruction in SCA takes place intravascularly.<sup>21,72</sup> Such intravascular hemolysis probably represents the shedding of microfilaments and progressive cellular fragmentation as the relatively rigid sickled cell passes through the microcirculation (page 824).

Extravascular hemolysis accounts for the

remaining two thirds of the destructive process.<sup>24</sup> Cells containing small Heinz-like bodies (page 824) are susceptible to phagocytosis by macrophages in the spleen and other RE organs.<sup>188,280</sup> In addition, a number of important biochemical and physical alterations adversely affect the survival of irreversibly sickled cells. As compared with other cells in the circulation of patients with SCD, ISC's are small cells with higher HbS concentrations, lower HbF concentrations, increased density,<sup>61</sup> decreased deformability, reduced membrane lipids,<sup>154</sup> normal 2,3DPG levels, reduced  $O_2$  affinity,<sup>293</sup> and increased content of calcium<sup>58a</sup> and increased cationic flux.<sup>331</sup> These features are similar to those described in preterminal, senescent normal cells (Chapter 5, page 201). Presumably, one or more of these changes stimulates phagocytosis by a reticuloendothelial macrophage.

### Vascular Occlusive Disease

Deoxygenation of blood from patients with sickle cell disorders brings about a pronounced increase in whole blood viscosity, which is due to the net effect of an increase in the internal viscosity of each cell.<sup>61</sup> In addition, sickled cells, being relatively rigid, are unable to alter their shape to the degree necessary to flow through capillaries 4  $\mu$ m in diameter or smaller (see Chapter 3, page 92). These two factors lead to dramatic reductions in blood flow within certain capillary beds when oxygen levels drop. The stagnation that follows leads to further reductions in oxygen tension and additional sickling, thereby aggravating the situation.<sup>129,157</sup>

Vascular occlusions in sickle cell disease typically occur in the microcirculation, particularly in vascular beds that are characterized by slow flow and high oxygen extraction. There appears to be a correlation between the frequency and severity of involvement of different organs and their circulatory characteristics. One frequently affected organ is the heart; because the myocardium extracts oxygen more efficiently than any other organ, there is almost always clini-

cal and pathologic evidence of thrombosis, infarction, and fibrosis in that organ as the result of vascular occlusion as well as the long-term result of anemia and iron overload.<sup>191</sup> In addition, the spleen, bone marrow, and placenta all are characterized by low blood pressure, slow blood flow, and high oxygen extraction, and all commonly participate in vascular occlusive episodes leading to infarction and fibrosis.<sup>81</sup> The effects of vascular occlusion in other tissues will be discussed below.

### Susceptibility to Infection

Patients with SCD have increased susceptibility to infection with certain bacteria and other infectious agents.<sup>20,95,307</sup> The most commonly involved sites are the lungs,<sup>21,162,295</sup> the genitourinary tract, and the bones and joints.<sup>70,139</sup> Less often the skin and the central nervous system are persistent sites of infection. There are several possible reasons for the increased propensity to infection: (1) When infection follows vascular occlusion, access of leukocytes to the involved area may be impeded. (2) Phagocytic function of the reticuloendothelial system may be impaired in patients with SCD, particularly in children with functional "hypoplasia."<sup>243</sup> (3) There is evidence for deficient opsonin activity in some children with SCD; possibly this abnormality represents a defect in the properdin system, which normally provides an important pathway for activation and fixation of the C3 component of complement to the surface of such bacteria as pneumococci. A decrease in this activity impedes ingestion of pneumococci by phagocytic cells.<sup>159,270,351</sup> (4) Defective granulation<sup>35</sup> and decreased phagocytic capability of the polymorphonuclear leukocytes have been described,<sup>85</sup> but the latter observation needs confirmation.

Alteration of one or more of these mechanisms and hypersusceptibility to infections seem to be more common in childhood than in adulthood, but in patients of all ages the differentiation between infarction, infection,

or the presence of both provides a difficult diagnostic problem.

### Clinical Characteristics of Sickle Cell Anemia (SCA)

#### Onset

Symptoms of SCA usually first become evident during the second half of the first year of life.<sup>240</sup> The lack of symptoms during intrauterine life and in the immediate postnatal period is accounted for by the presence of larger amounts of fetal hemoglobin than are present later. As the adult pattern of hemoglobin becomes established, and the proportion of abnormal  $\beta$ -chains increases, the individual becomes more and more susceptible to the pathophysiologic events that cause clinical symptoms. By about six months of age, the child's cells have acquired the adult complement of HbS. There is, however, some variation in the age of onset of symptoms; this ranged in one series from three months to 15 years.<sup>120</sup>

Just as the age of onset of symptoms varies, so does the severity of the disease. The usual presentation is that of a patient with severe hemolytic anemia, painful vaso-occlusive episodes, and multiple organ involvement. Much less often, an individual who inherits HbSS has only moderate anemia, few symptoms, and a nearly normal life span. Some patients with what appears to be mild sickle cell anemia may in fact be doubly heterozygous for combinations of HbS and  $\beta$ - or  $\alpha$ -thalassemia, or have HbSD disease, or HbS associated with hereditary persistence of fetal hemoglobin (page 875).<sup>275</sup> In other instances the mild nature of the disease remains unexplained. In a group of patients without evidence for double heterozygosity, attempts to relate the severity of symptoms to various laboratory findings were without success. Neither the hemoglobin concentration, reticulocyte count, nor the HbA<sub>2</sub> or fetal hemoglobin levels could distinguish patients with relatively benign manifestations from those with more severe SCA.<sup>320</sup>

In children, the onset of SCA is often heralded by irritability and complaints of pain in joints, the back, the legs, the abdomen, or chest. In addition to such painful episodes, children manifest other characteristic clinical syndromes. A most distinctive one is dactylitis (*the hand-foot syndrome*). This, in about one third of the patients, is the first serious symptomatic episode. Typically, the dorsa of the hands and/or feet are swollen, non-erythematous, and exquisitely painful. Fever and leukocytosis are common and the more severe symptoms last for 10 to 14 days. Roentgenologic changes, usually detectable after about a week, consist of periostitis and osteolysis in addition to the soft-tissue swelling. The episodes are not altered by specific medication. They are self-limited and rarely occur after the patient is three years of age.<sup>219,339</sup>

As they grow older, the patients become susceptible to the symptoms that attend involvement of various organs; the painful crises that typify sickle cell anemia in adolescent and adult patients make their appearance.

### Growth, Development, and Life Span

The growth pattern of children with SCA differs from that of normal children. The afflicted children are thinner than age-matched normal children; growth is retarded in 94% of them<sup>298,350</sup> and their mean weight is 2 SD below the mean weight of normal children. Sexual and skeletal maturation may be delayed. Adult patients often are underweight and have relatively long extremities, narrow hips, and an accentuated lordotic curvature. However, exceptions to the typical SCA habitus are common enough to suggest that the classic descriptions of the thin, asthenic, long-limbed, short-trunked individual have overemphasized this feature.

Changes in the skeleton may occur as the result of bone marrow hyperplasia, the expansion of medullary spaces leading to prominence of the frontal bones or to maxillary bone overgrowth (gnathism).<sup>174</sup> Such abnormalities probably are less striking today

than they were a decade ago, possibly because of improved nutrition, decrease in the number of infections, and better management of parasitic infestations.<sup>174,311</sup>

Adequate data concerning the life span of patients with sickle cell disease are not available for large populations in Africa<sup>174,230</sup> or in the Americas, but one study indicated that more than 50% of patients with SCA are older than 10 years of age and thus it is apparent that the prognosis at birth is not entirely hopeless.<sup>300</sup> Although completely satisfactory data for average survival are not available, it appears that most patients do not survive beyond the second and few survive beyond the fourth decade of life. In one study the median survival was found to be 14.3 years; approximately one fifth of the deaths occurred in the first two years of life, one third before the fifth year, one half in patients between ages 5 and 30 years, and one sixth in those older than 30.<sup>81</sup> SCA has been reported, however, in patients of relatively advanced age,<sup>1,56</sup> and, in Jamaica, 121 patients over 30, 43 over 40, and 13 over 50 years of age were observed.<sup>300</sup>

### Sickle Cell Crises

The term "sickle cell crisis"<sup>79</sup> may have been used too freely in discussions of the clinical aspects of SCA, and this practice has sometimes tended to blunt the physician's search for an intercurrent disease, unrelated to the sickle cell disorder. The phrase "sickle cell crisis" is probably most appropriate when used to refer to the uncomplicated, painful vaso-occlusive episodes. A typical crisis is best described as an episode of moderate to severe pain, resulting from occlusion of portions of the microcirculation. Such episodes are characteristic of the sickle cell disorders and occur only rarely in association with other hemolytic disorders. The pain, which is gnawing, gradually increases in severity over a period of hours and commonly involves the extremities, especially the tibial and periarticular areas, the abdomen, chest, and back.<sup>53,79,174</sup> Once the symptoms have appeared, they are unlikely to change in

character. They may last only a few hours but, more often, they persist for a few days or weeks. The pain is periodic and usually abates gradually. The episode may be preceded by an infection. Fever, usually of low grade and not associated with chills, may occur. There tend to be no specific physical or laboratory findings that identify the episode as a painful crisis; rather, the very absence of such specific findings is important in the recognition of a vaso-occlusive painful crisis.<sup>15</sup> The diagnosis is greatly facilitated by prior experience with the patient since many have a stereotyped pattern of pain that is recognized by both patient and physician.

The diagnosis requires particularly careful clinical evaluation because patients with SCA are more than normally susceptible to other painful disorders. Thus the painful crisis must be differentiated from pneumonia, pulmonary infarction, gout, acute rheumatic fever, rheumatoid arthritis, acute pyelonephritis, cholecystitis, and a variety of other conditions.

### Cardiovascular Manifestations

Cardiovascular abnormalities are constant features of SCA and the other symptomatic sickle cell disorders. The heart is subjected to repeated episodes of acute and chronic stress, and the extent and type of vascular disease seem unique to the sickle cell disorders as compared with most other types of chronic hemolytic anemia.<sup>88,170,191</sup> Early in childhood, patients with SCA develop cardiac enlargement, and murmurs are almost always present. Common cardiorespiratory symptoms include exertional dyspnea, palpitation, and pleuritis. Rarely the patients experience pain that suggests myocardial ischemia. All of the features of a hyperdynamic circulation may be observed. The arterial pulses are full and brisk, reflecting a widened pulse pressure. The jugular venous pulse usually is normal, but occasionally it is characterized by an exaggerated A wave. The precordium usually is hyperactive, a manifestation of biventricular hypertrophy. The apical impulse may be

enlarged, sustained, and displaced to the left and an anterior parasternal lift is common.

Systolic murmurs can almost always be detected. These tend to be quite loud and usually are located near the left sternal border with occasional radiation to the entire precordium. Often pansystolic, they may mimic the murmur of mitral regurgitation and may be associated with an ejection click. The systolic impulse in the second left intercostal space is often visible and sometimes palpable, a finding that represents the transmission of pulmonary artery pulsations to the chest wall. Although these findings suggest pulmonary hypertension, the pulmonary artery pressure usually is normal.<sup>306,317,332,334</sup> The auscultatory events reflect the rapid ventricular filling. A loud third heart sound is almost invariably heard and the fourth heart sound often is also detected.

Radiologic examination reveals cardiac enlargement of moderate or severe degree involving all chambers, and the silhouette is somewhat globular (Fig. 25-2). The pulmonary artery segment of the border of the left side of the heart frequently is conspicuous, and other pulmonary vascular shadows are prominent. The right and left main branches of the pulmonary arteries may be markedly enlarged.

The electrocardiogram commonly shows abnormality,<sup>334</sup> but without specific diagnostic findings. Electrocardiographic evidence of left ventricular hypertrophy is obtained in about one half of the adult patients and signs of right ventricular overload are found in about 10 to 15%. The multiplicity of cardiovascular abnormalities attributable to SCA makes the differentiation from such disorders as rheumatic fever, congenital heart disease, and bacterial endocarditis particularly difficult. A number of reports document the concurrence of SCA and rheumatic heart disease, atrial septal defects, pulmonary stenosis, or tetralogy of Fallot,<sup>170,202,208,232</sup> but there is no reason to believe that these conditions are more frequent in SCA than in the general population. They are best differentiated by cardiac hemodynamic studies or by angiography.

Fig 25-2. Teleoroentgenogram of the heart and great vessels in a patient with SCA. The heart is markedly enlarged with prominent left ventricle and right atrium. There is a slight prominence in the region of the pulmonary conus.

### Pulmonary Signs

Since the sickling phenomenon depends on deoxygenation of hemoglobin, adequate pulmonary function and oxygenation are essential to the well-being of the patient with SCA.<sup>42,214</sup> The major acute pulmonary disorders in these patients are *infectious* and *vascular occlusive episodes*. These may occur separately or in combination and may be extremely difficult to distinguish from each other. Indeed, they may be pathogenetically interrelated and concurrent.<sup>21</sup> *Chronic pulmonary disease* may result from repetitive episodes of infection and from vascular occlusion leading sometimes to chronic pulmonary arterial hypertension and cor pulmonale. The most common pulmonary functional abnormality is decreased arterial oxygen tension and desaturation of arterial blood.<sup>42,43,44,157,317</sup>

Of 164 patients with SCA and evidence of bacterial pneumonia, pneumococcus was recovered from sputum or nasopharyngeal cultures in 67, and from the blood in 11. Other causative organisms included *Mycoplasma*

pneumoniae, *Haemophilus*, the *Salmonellae*, *Escherichia coli*, and, less frequently, other gram-negative rods and gram-positive cocci.<sup>19</sup> In patients with SCA, bacterial and mycoplasmal pneumonias last longer than in normal subjects; furthermore, infiltrates commonly affect more than one lobe of the lungs, and resolution of the infiltrates is slower.<sup>19,249,307</sup> It is likely that impaired access of oxygen to the infected lung tissues enhances the sickling phenomenon with resulting local, microvascular thrombotic disease. The bacterial pneumonias may be associated with bacteremia and metastatic infections, and, therefore, with disseminated intravascular coagulation.<sup>162,264</sup> They require prompt identification and energetic antimicrobial therapy. The aggressive use of diagnostic techniques, including transtracheal or transthoracic needle aspiration of bronchial material or lung tissue as well as bronchial brushings, is warranted to establish a specific diagnosis and to allow specific therapy.

Pulmonary vascular occlusion occurs commonly in the absence of infection, and sudden

death following large vascular occlusion has been reported.<sup>131</sup> Patients with SCA develop *in situ* vaso-occlusive disorders produced by the sickling of relatively deoxygenated blood in the pulmonary arteries; embolization to the lungs of clots formed in distal veins also may occur.<sup>44</sup> In addition, bone marrow and fat emboli from infarcted marrow are known to have produced vascular pulmonary disease.<sup>81,233,316</sup> The differentiation of primary infection from vascular occlusion is difficult. Clinical features that favor a diagnosis of pulmonary thrombosis are associated pain in the abdomen or extremities, absent or minimal temperature elevation, a lack of chills, inability to identify an offending organism, and perhaps the presence of poikilocytes ("blister cells") and an increased number of fragmented cells (ISC's) in the blood.<sup>16,21,165</sup> Pulmonary radioisotopic scans so far have not proved to be very useful in differentiating thrombosis from infection. Experience is inadequate to allow evaluation of pulmonary angiography.

Pulmonary mechanical function usually is impaired at least modestly and sometimes strikingly in patients with SCD. Typically, there is a modest reduction in vital capacity and total lung capacity.<sup>44,96,212</sup> Occasionally there is obstructive lung disease, and gas mixing and gas exchange almost always are abnormal. Arterial oxygen tension ranges from 70 to 90 mm Hg, accompanied by a reduction of arterial saturation usually ranging from 80 to 90%, but occasionally falling to even lower levels.<sup>44,317</sup> Blood may be shunted through an undefined pathway or there may be disparity between ventilation and perfusion. The combination of these various processes results in a decrease in the available cross-sectional, pulmonary vascular tree and, at times, an increase in pulmonary artery pressure. In some patients the pulmonary hypertension contributes to the cardiac disease.

#### Abdominal Involvement

Episodic abdominal pain is common in patients with SCA and is a frequent feature of the painful vaso-occlusive crises (page

828). The organs most often involved include the liver, gallbladder, and spleen, whereas the stomach and intestines seem to be relatively infrequent sites of symptomatic disease.

The *liver* usually is enlarged, but is not tender to the touch. However, it may enlarge acutely and become quite tender during periods of crisis. Subcapsular infarcts may occur and these may produce right upper quadrant pain and transient rubs. Liver abscesses have been reported, apparently the result of bacterial inoculation of infarcted tissue.<sup>40</sup>

In older patients, a diffuse or nodular type of cirrhosis may be found.<sup>36,115</sup> Various forms of intercurrent acute liver disease occur with increased frequency in patients with SCA. These include viral hepatitis,<sup>17</sup> drug-induced liver disease, hemosiderosis, and the complications of cholelithiasis.<sup>115,271</sup>

About 30 to 60% of patients, depending on age, develop gallstones but not more than 10 to 15% have symptoms that may be attributed to disease of the biliary tract.<sup>18,48,231</sup> The gallstones usually are radiolucent, and the gallbladder is ordinarily visualized by radiopaque dye studies, despite the intermittent hyperbilirubinemia.<sup>123</sup> The clinical manifestations of cholecystitis are similar to those in patients with cholecystitis who do not have SCA. Because of the high incidence of cholecystitis in patients with SCD and difficulty in the differential diagnosis of right upper quadrant pain in these subjects, some have suggested elective cholecystectomy for SCD patients with cholelithiasis.<sup>18</sup> The expected operative morbidity and mortality are probably not greater than those of age-matched patients who do not have SCD.

The *spleen* and *splenic function* almost always are altered in SCA. Splenic function may be increased, or decreased, and may change rapidly, or, in some patients, over long periods. Most commonly in childhood, the spleen is enlarged without evidence of hyperfunction or hypofunction. Occasionally, in childhood, the *splenic sequestration syndrome*<sup>45</sup> occurs. The spleen undergoes rapid enlargement from the acute entrapment of red cells, with resulting systemic hypovolemia, severe abdominal pain, more severe ane-

mia, and other findings indicative of an abdominal catastrophe.<sup>151,210,291</sup> "Hyposplenism" may be suspected when the spleen is *not palpable*, or even when it is palpably enlarged but pneumococcal infection occurs, or when there is thrombocytosis or marked leukocytosis and target cells and increased numbers of nucleated red cells and Howell-Jolly bodies are found in the blood.<sup>210,212,213</sup> By adolescence, the spleen is enlarged in fewer than 15% of SCA patients in the United States.<sup>210</sup> When splenomegaly is detected in late adolescence or adulthood, the patient should be studied for the possibility of doubly heterozygous disease (pages 844, 872) or the concurrence of another illness. In adult patients, the spleen usually has undergone repeated episodes of thrombosis, infarction, and, occasionally, military calcification ("autosplenectomy").<sup>78,134,316</sup> Occasionally in SCA, but more commonly in the other sickle cell disorders and in sickle cell trait, acute splenic infarction is precipitated by exposure to high altitude.<sup>144,310</sup>

### Bone and Joint Changes

The dactylitis seen in infants and young children with SCD (page 828) is one of the many changes that occur in the bones and joints of most patients with SCD. The slow sinusoidal circulation of the bone marrow provides an ideal vascular bed for the sickling phenomenon and *bone marrow infarction is a common event. Evidence that bone marrow circulatory occlusion occurs in SCA includes the frequency of bone pain during painful crises, the occurrence of bone marrow embolization, the radiologic changes in the bones, and the abnormalities found on histologic examination of bone marrow biopsy specimens as well as at autopsy.*<sup>58,81,316</sup> The vascular occlusions cause avascular necrosis of the hip or shoulder, which may mimic the clinical and radiologic appearance of Legg-Calvé-Perthes disease.<sup>63</sup>

Bone disease in SCD often is associated with degenerative changes of cartilage and synovial membranes, which cause deformities of adjacent joints. Marrow infarction, necrosis, and the healing process are often followed

by new bone formation which produces unique radiologic abnormalities (Fig. 25-3). When larger segments of cortical bone undergo infarction, periosteal reaction and subperiosteal calcification follow. The bodies of the vertebrae contain hyperplastic marrow and the distorted trabecular structure may be inadequate for normal weight-bearing. In adults the vertebral bodies may become compressed and also develop concave central regions, a deformity known as "fish-mouth vertebrae."<sup>80</sup> Marrow hypertrophy in the flat bones causes widening of the diploic space; this produces the thickening of the frontal bones and the maxillary bone overgrowth mentioned earlier (page 828).<sup>174</sup> In Africa, *osteomyelitis* is much more common in patients with SCA than in persons who do not have this disease.<sup>174</sup> There, and also in the United States, the most common infecting agents are the various species of salmonellae. *Staphylococcus aureus* also is a common causative organism.<sup>80,91,139</sup>

The joints are affected by a number of disorders including avascular necrosis of bone adjacent to a joint, gout,<sup>13</sup> septic arthritis, possibly hemarthrosis and hemosiderosis, and a peculiar arthritis in which the knees and elbows are commonly involved. The arthritic episodes are painful and often are associated with fever, leukocytosis, and joint transudates. Synovial biopsies show obliterated vessels without evidence of acute inflammation or marrow embolization. Sickled erythrocytes are found in the joint fluid.<sup>287</sup> In adults, there may be deformations of the hands and feet, with shortening of digits, apparently the remote sequelae of the dactylitis of childhood.<sup>298</sup>

### Genitourinary Signs

SCA is associated with a variety of defects in renal function.<sup>46,281</sup> In most patients with SCA and in some with sickle cell trait, the ability to concentrate urine<sup>167,244</sup> and to excrete hydrogen ion<sup>113,129,140</sup> is impaired. These abnormalities usually are not severe and produce no symptoms. The concentrating defect seems to be related to the age of the individual and the severity of the dis-

Fig 25-3 Sickle cell anemia. A, Femur. The cortex is thinned and the normal bony architecture is disturbed. Adjoining small areas of translucency there are areas of sclerosis. B, Tibia and fibula. Marked thinning of the cortex of the bones as well as periosteal reaction and disarrangement of the trabeculae. The latter changes and the extensive coarseness of the cortical layers suggest that the bone is involved from within.

ease. It is reversible in young but not in older persons by the transfusion of normal blood.<sup>167,318</sup> For this reason, it has been suggested that, in early life, blood flow in the minute vessels of the renal medulla is impaired by the presence of sickled cells, and, later, a portion of the vasa recta is obliterated.<sup>168</sup>

Hematuria is common, and may be brisk and prolonged. The hemorrhages may come from one kidney or both or occur in alternating fashion. The bleeding possibly results

from congestion and thrombosis of the renal mucosal vessels or, less often, comes from the papillae.<sup>6,112,127,220</sup> The rapid red cell turnover in sickle cell disease is attended occasionally by hyperuricemia, which, in some instances, may cause attacks of gout and, less commonly, urate nephropathy.<sup>109,337</sup>

The nephrotic syndrome occurs only rarely, but less severe vascular and glomerular abnormalities are considerably more frequent. Glomerular basement membrane changes have been detected in young pa-

tients,<sup>252</sup> and similar but more advanced lesions were found in three patients with the nephrotic syndrome.<sup>203</sup> It is possible that the nephrotic syndrome is caused by a combination of vascular thrombotic events and the deposition of non-heme iron in the glomerular epithelium and the proximal tubular epithelium.<sup>10,252</sup> Alternatively, it may result from renal venous thrombosis or from unrelated disease.

Ultimately the majority of patients with SCA develop moderate or severe renal functional impairment, but end-stage renal failure is an unusual cause of death.<sup>328,337</sup>

*Priapism* of a severe degree is uncommon, but many patients relate that they have had transient episodes. The engorgement of the corpora cavernosa usually is not accompanied by dilatation of the glans penis. There are no recognized precipitating causes. The episodes last for hours or for days.<sup>105,165,373</sup> Numerous irreversibly sickled cells and clots have been found in the distended sinuses when therapeutic needle aspiration or incisional drainage has been carried out.<sup>81</sup> The repetitive trapping of cells in the corpora cavernosa, with or without surgical intervention, may lead to fibrosis of the septa and irreversible damage to the arteriovenous mechanisms of penile erection.<sup>314</sup>

## Neurologic Manifestations

Infections occur in the central nervous system, but most of the neurologic damage results from vascular disease. Although it has been widely held that the neurologic abnormalities are caused by occlusions of venous capillaries and precapillary arterioles, both cerebral angiography and pathologic studies have demonstrated thrombotic involvement of medium and large vessels. In an angiographic study, partial or complete occlusion

of large cerebral vessels was found in six of seven patients with SCA who manifested central nervous system dysfunction.<sup>322</sup>

These angiographic findings are in keeping with the high incidence of central nervous system abnormalities in patients with SCA. Thus, in a study of 89 patients observed for five years, hemiplegia, usually in conjunction with other neurologic symptoms, occurred in 17%; convulsions were noted in 12%, disorders of consciousness in 9%, and visual disturbances in 5%. Intracranial hemorrhages and spinal cord infarction also have been observed.<sup>255</sup> Diagnostic evaluation may require not only routine radiologic procedures and cerebrospinal fluid examination, but also radioisotopic brain scans and cerebral angiography. Angiographic contrast media have the potential for initiating sickling and careful attention must be given to proper preparation of the patient and to the rate at which dye is introduced into the artery.<sup>39</sup>

Peripheral neuropathy is no more common in SCA patients than in the normal population, and intellectual capacity and ability for mentation and scholastic activities seem unaffected except when specific cerebrovascular neurologic damage has occurred.

## Ocular Manifestations

The ocular manifestations of SCA are due either directly to involvement of the vasculature or are the sequelae of vascular damage.<sup>11,66,69,190,343</sup> The conjunctival vessel changes, most often seen in the lower temporal bulbar conjunctivae, consist of dilated segments of capillaries or veins that are packed with sickled cells and have a comma-shaped or curlicued appearance (Plate XII, A).<sup>58,237</sup> These lesions are best seen with the slit-lamp biomicroscope and are rare in disorders other than SCA, HbSC disease,

## PLATE XII

*Common ocular abnormalities in sickle cell anemia* The "comma" vascular sign shown in A is a superficial conjunctival vessel that contains densely packed sickled cells. B shows the interrupted or segmental flow of cells characteristic of sludged blood in a superficial conjunctival vessel. C shows the widened veins and tortuous large vessels of the retina. In D is seen a large preretinal hemorrhage, of approximately two weeks' duration, which has undergone partial resorption and has exposed a darkened area that was the probable site of intraretinal hemorrhage. E shows a stained blood smear of a patient with sickle cell anemia. In F an old pigmented choroidal scar is shown. (Photographs by Professor Mansour Amaly, The George Washington University Medical Center.)

# PLATE XII

E

F

HbSD disease, and HbS-thalassemia.<sup>65,111</sup>

Repeated *vitreous hemorrhages* may arise from retinal vascular anomalies, from areas of neovascularization, or from acute occlusion of large veins. The blood may be gradually resorbed, or become organized to form fibrovascular membranes with attachments at the base to the retina.<sup>66</sup> Contracture of these membranes may cause giant retinal tears or retinal detachment with recurrent hemorrhages into the vitreous. Obstruction of retinal vessels may lead to hemorrhage or to thrombosis followed by the formation of diffuse patchy areas of devascularization. Retinal vessels may be tortuous and looping. These "horseshoe"-shaped veins, the microaneurysms, and the heavily pigmented areas of prior chorioretinal infarction ("sunburst" lesions) are typical fundusoscopic findings in the sickle cell disorders (Plate XII). When retinal arteriolar occlusions occur, arteriovenous anastomoses may form, followed by a quite typical process of neovascularization that produces vessels resembling "sea fans,"<sup>110,111</sup> lesions which are much more common in HbSC disease than in SCA.<sup>110</sup>

### Pregnancy and HbS

Pregnancy and SCA affect one another adversely. The highest morbidity and mortality were recorded in earlier reports,<sup>73,92,268</sup> the more recent observations suggesting much lower rates.<sup>141,245</sup> Complications in the first six months of pregnancy are infrequent except that anemia may become more severe, and there may be an increased incidence of pyelonephritis, hematuria, and painful crises.<sup>141,245</sup> During the latter months of pregnancy and throughout parturition and the first few postpartum days, the patient is at greatest risk. Mortality rates ranging from 0 to 25% have been reported. Heart failure, which occurs in 2 to 20% of SCA patients, may appear for the first time during pregnancy; about 10% of pregnant SCA patients develop phlebitis, and pulmonary infection and/or infarction occur in 5 to 40%. Toxemia is common and postpartum puerperal endometritis occurs in about 20% of these subjects.<sup>47,73,134,141,245,266,268</sup>

There is little information regarding fertility (page 828) in patients with SCA, but reproduction rates probably are decreased. The slow, sinusoidal circulation of the placenta and the high degree of oxygen extraction provide an excellent milieu for sickling, thrombosis, and hemolysis.<sup>81</sup> The fetal risk is high, with an overall salvage rate of only about 58%, compared with 87% in normal women. The fetal wastage is due to a combination of abortions and stillbirths.<sup>134,141,245</sup> The incidence of premature birth is increased and the birth weights of viable infants are decreased.<sup>130</sup> There is no evidence of an increased incidence of congenital malformations or of particular susceptibility of the offspring to other medical disorders.<sup>245</sup>

In pregnancies of patients with sickle cell trait a miscarriage rate of 9.7% was reported, as compared with a rate of 2 to 4% when one or neither parent had the sickle cell trait.<sup>277</sup>

Although the risk of serious complications during pregnancy in patients with HbSC disease and HbS- $\beta$ -thalassemia is increased, current data suggest a lower maternal mortality rate, fewer episodes of heart failure, painful crises, or puerperal sepsis, and a higher incidence of toxemia than in SCA, but the rates of puerperal infection and pulmonary disease are about equal in the two conditions. The fetal salvage rate in patients with HbSC disease and HbS-thalassemia is about 70% and birth weights are normal.<sup>135,141</sup>

### Laboratory Findings

Severe or moderately severe normocytic, normochromic anemia is present during the entire life of patients with SCA. Red cell indices usually are normal, but the MCV may be increased or reduced. It is possible to separate the red cells into several populations on the basis of cell density.<sup>29,61,293</sup> Reticulocytes are least dense, mature biconcave discs are intermediate, and the irreversibly sickled cells are most dense. The number of ISC's in the blood varies considerably from one patient to another.<sup>302</sup>

The red cells of patients with SCA show great *morphologic distortions* that are best seen when the cells are examined by phase or

**Fig 25-4.** Erythrocytes from a patient with SCA examined with scanning beam electron microscopy. **A**, Oxygenated blood. The red cells appear normal except for one microspherocyte. There are three leukocytes in the field. **B**, Oxygenated irreversibly sickled cells are smooth in texture and outline, but are ovoid or boat like in shape. **C**, Partial deoxygenation causes the cells to assume bizarre shapes with spikes, spicules, and filaments that protrude from the cells. **D**, More complete deoxygenation causes the cells to assume sickled shapes with longitudinal surface striations. **E**, At higher magnification the cells have a sculptured texture. Multiple spike-like protrusions are seen at the polar ends of one cell. **F**, Complete deoxygenation of acanthocytic sickle cells produces numerous short protrusions and occasional long filaments.

scanning electron beam microscopy (Fig. 25-4), but also are very evident on conventional blood smears.<sup>154,236</sup> (Plate XII.) Most of the poikilocytes are cigar-shaped, crescent-like, or ovalocytic, but acanthocytes and target cells are also found. Many of the poikilocytes show indentations, but scanning electron beam microscopy of the membrane has not shown a qualitative difference from normal or other cells. Nucleated red cells and red cells with basophilic stippling, diffuse polychromatophilia, Howell-Jolly bodies, Pappenheimer's bodies, and Cabot rings usually are present. The presence of large numbers of cells with inclusions suggests the combination of an accelerated rate of release of cells and a hypofunctional spleen. Examination of red cells by electron microscopy in the oxygenated unsickled state reveals the occasional presence of small, dense aggregates of hemoglobin adjacent to the membrane; these have the morphologic characteristics of small Heinz bodies.<sup>188,286</sup> The morphologic alterations are accompanied by other abnormalities, including decreased mechanical fragility and abnormalities of osmotic fragility, which reflect the variety of stages of red cell maturation and the differently shaped cells that were described above. The sedimentation rate in sickle cell anemia is consistently decreased.

Erythrokinetic studies performed in the steady state reflect a four- to five-fold increase in rates of red cell production and erythron iron turnover, and a five- to ten-fold decrease in red cell life span. As measured by <sup>3</sup>H- or <sup>32</sup>P-labeled diisopropylfluorophosphate (DFP), destruction of red cells is random rather than senescent (Chapter 5).<sup>24,26,205,215</sup> This pattern of cell loss is compatible with the observations that the number of irreversibly sickled cells (ISC) is inversely correlated with cell life span and that such cells are of various chronologic ages.<sup>302</sup> Endogenous carbon monoxide production and excretion of urobilin and urobilinogen in the urine and feces are increased.

The erythrocyte production rate may be impaired by folate deficiency,<sup>161,194</sup> infection, inflammation, the ingestion of alcohol<sup>138</sup> or medications, aplastic crises,<sup>185</sup> or the pro-

Fig. 25-8. Sickled red corpuscles from a patient with SCA. The cells were washed several times with normal saline solution and the cell suspension was then allowed to remain under oil. After time had been allowed for sickling to occur, formalin was added in order to fix the cells in their abnormal shape. A smear was then made and prepared with Wright's stain ( $\times 1050$ ) (Prepared by Dr. Irving J. Sherman.)

longed administration of oxygen at high concentration.<sup>262</sup> In the patient with a red cell life span of approximately 10 to 15 days, a decrease in rate of cell formation produces a dramatic aggravation of the anemia in a short time. Thus, a rapid fall in hematocrit may occur during an acute infection and is not necessarily caused by increased hyperhemolysis<sup>413</sup> (Chapter 24).

The red cell destruction is partially intravascular, thereby producing an elevation of plasma heme proteins and decreased haptoglobin concentration.<sup>72</sup> Serum levels of non-conjugated bilirubin are moderately increased.

The white blood cell count is often elevated, usually because of increased neutrophils. Each patient tends to maintain a typical leukocyte pattern, except during periods of painful crisis, infection, folate deficiency, or other intercurrent disease. It is important that the usual leukocyte pattern of the patient be known since leukocytosis of 16.0 to

$20.0 \times 10^9$  cells/l often is present during relatively asymptomatic periods in some patients and this may reflect "asplenia" rather than inflammatory or infectious disease.

Studies of neutrophil kinetics with DF<sup>32</sup>P indicate that the circulating granulocyte pool is normal or enlarged, but the total granulocyte pool is not increased to the same degree. This discrepancy indicates a shift from the marginal to the circulating blood granulocyte compartment (Chapter 6). The disappearance time of neutrophils is slightly reduced; the granulocyte turnover rate is increased.<sup>35</sup>

Platelet counts may be within normal limits or increased, but the number of platelets may become decreased when there is folate deficiency or during an aplastic crisis. An increase in platelet numbers suggests reduced splenic sequestration.<sup>248</sup> Megakaryocytes or megakaryocytic fragments may be found in the blood during episodes of bone marrow infarction.<sup>55</sup> The rate of platelet turnover has not been studied extensively, but the available information suggests that platelet consumption increases in patients with thrombotic disease, including those with sickle cell disorders.<sup>130a</sup> Platelet function seems to be normal. Factor VIII activity may be increased, but factors IX, XI, and XII are normal.<sup>364</sup>

The bone marrow erythroid mass is increased. Maturation of the erythroblasts is normal and there is little to distinguish the bone marrow from that found in association with other severe chronic hemolytic anemias other than the presence of sickle cells or of long filamentous strands of what appears to be erythrocyte cytoplasm. These strands may extend across the whole oil-immersion field and may be no more than 2  $\mu$ m in diameter.

Despite the prolonged period of maximal stimulation with resulting bone marrow hyperplasia, there is no evidence of bone marrow failure, nor is there evidence to indicate that the constant hematopoietic stimulation induces neoplasia. The incidence of aplastic anemia, myelofibrosis, or leukemia does not seem to be greater in SCA patients than in normal populations. Myeloma has been noted in patients with SCA.<sup>327a</sup>

## Laboratory Tests for Sickling

In SCA the number and character of sickle cells in stained blood smears may not be sufficiently striking to warrant a diagnosis. Furthermore, sickled cells are rarely, if ever, seen in blood smears from persons with sickle cell trait. However, the sickling phenomenon may be induced by a variety of maneuvers, which depend on the deoxygenation of hemoglobin. It may be induced by sealing a drop of blood under a coverslip to exclude oxygen, or by adding agents that induce chemical deoxygenation, such as 2% sodium bisulfite ( $\text{Na}_2\text{S}_2\text{O}_3$ ), or a preparation of sodium dithionite ( $\text{Na}_2\text{S}_2\text{O}_4$ ); or by gaseous displacement of oxygen by mixtures of nitrogen and carbon dioxide. The degree and rapidity of the sickling phenomenon depend primarily on the amount of sickle hemoglobin and the degree of deoxygenation.<sup>123</sup> Cells containing other hemoglobins in which the beta  $6^{\text{Olu}} \rightarrow \text{Val}$  substitution is present, such as HbC<sub>Georgetown</sub> and HbS<sub>Memphis</sub>, also exhibit the sickling phenomenon. Under conditions of severe deoxygenation, sickling takes place in cells that contain HbI; under conditions of hyperoxygenation, deer cells will undergo sickling.<sup>151</sup>

There are a number of commercially available preparations for the detection of sickle hemoglobin; these depend upon the decreased solubility of deoxygenated HbS in high phosphate buffer solutions. They have obvious advantages in laboratories in which only sporadic testing for SCA is required, but the reliability of the commercially available kits varies from excellent to poor, and, because of the cost of the commercial products, laboratories in which frequent testing for SCA is performed prepare their own reagents.<sup>283a</sup>

The available screening tests utilize the classic sickle-cell preparation described above, the solubility test,<sup>146a</sup> or hemoglobin electrophoresis (Chapter 24). Each of these tests has particular advantages and pitfalls, but the most reliable primary screening method is probably electrophoresis on cellulose acetate.<sup>217, 256</sup> This method allows detection of abnormal hemoglobins other than HbS as well as identification of some of the

doubly heterozygous forms of sickle cell disorders. Whole blood, dried blood specimens, or hemoglobin solutions may be used.<sup>97</sup> When electrophoresis is employed as a primary screening method, a solubility test may be used to identify the occasional persons who will be found heterozygous for HbD (page 846). Identification of abnormal hemoglobins in more precise fashion than that provided for by cellulose acetate electrophoresis and tests of solubility requires family studies and laboratory technology not available in the usual screening program.

### Sickle Cell Trait and Screening

The term "sickle cell trait" refers to the inheritance of one determinant for the abnormal beta 6<sup>Val</sup> HbS chain, and one determinant for normal beta 6<sup>Glu</sup> HbA. The cells of such individuals contain both HbA and HbS but have more HbA than HbS.<sup>37</sup> The ratio of HbA to HbS is related to the synthetic rates of hemoglobins A and S rather than to selective destruction of one of them.<sup>28</sup>

Red cells containing both HbS and HbA require much greater deoxygenation than do those from patients with sickle cell anemia (HbSS) before sickling occurs. As mentioned above, sickled cells are rarely found in the blood of a person with the sickle cell trait<sup>121</sup> and there are few established complications attributable to this trait.<sup>71</sup> Hyposthenuria,<sup>23</sup> spontaneous hematuria,<sup>46,112</sup> renal papillary necrosis,<sup>127</sup> priapism, central retinal artery occlusion,<sup>69</sup> splenic infarction,<sup>231,310</sup> splenic rupture with bacterial endocarditis, and greater frequency of asymptomatic bacteriuria in women than in the general population<sup>346</sup> have been reported in persons with the sickle cell trait. Retrospective studies show the same overall mortality rate in persons with the sickle cell trait as in normal persons.<sup>12,132</sup> However, complications may be more frequent and illness may be more severe among patients with the sickle cell trait and pulmonary disease, thrombophlebitis, or diabetic vascular disease than in those without this trait.<sup>132</sup>

Four deaths among soldiers undergoing strenuous physical conditioning at an altitude

of 4060 feet were attributed to the sickle cell trait.<sup>160</sup> In areas where cerebral malaria (*Plasmodium falciparum*) is endemic, the mortality rate among infants and young children with the sickle cell trait is less than in those with HbA<sup>7</sup> (page 813). In temperate climates, however, the sickle trait seems to confer no physiologic advantages.

A number of large-scale screening programs designed to detect heterozygotes for abnormal hemoglobins and to inform them of their hemoglobin type have been carried out, primarily among black populations.<sup>182,274,275,344</sup> The major purpose of such programs is to provide affected individuals the opportunity to determine the probability of having a child with homozygous disease. Effective education of those who are screened is necessary in order to make clear to them the mode of inheritance of abnormal hemoglobin genes and the difference between heterozygosity and homozygosity. Screening programs not associated with effective counseling will sow confusion and may even be harmful, especially for the well child who is presented with the "stigma" of having an inherited illness. Furthermore, since the interaction of other abnormal hemoglobins or thalassemia with HbS may have serious consequences, any screening program designed to provide genetic counseling should employ techniques that will detect these conditions as well.

### Morbid Anatomy

In SCA the bone marrow is hyperplastic, and extramedullary hematopoiesis frequently is evident in the lungs, liver, and retroperitoneal and perirenal regions. Hemosiderosis of varying severity is present in the liver, the spleen, kidneys, lymph nodes, bone marrow, and heart, even in patients who have received relatively few transfusions. Various phases of tissue infarction and reparative fibrosis may be observed in almost any tissue.<sup>81,89,169,316</sup>

The heart is almost always dilated and enlarged. Hypertrophy of fibers and a variety of nonspecific degenerative changes are found in the myocardium, together with extensive *myofibrillar* fibrosis involving the right and left

ventricular muscle and the interventricular septum. The nuclei of muscle cells appear normal, but there are paranuclear deposits of hemofuscin pigment.<sup>17a,191</sup> Cardiac hemosiderosis, so common in thalassemia, is less striking in patients with SCA. The endocardium is typically free of lesions, as are the coronary arteries and large veins of the heart. When pericarditis is present it is usually due to other disease processes or is secondary to pulmonary or pleural infection.

The *lungs* show acute and chronic changes that are the result of infection, infarction, and cardiopulmonary failure.<sup>42,81</sup>

In the *kidneys* there are dilated glomerular and peritubular capillaries that are engorged with sickled cells, as well as enlarged glomeruli, foci of interstitial hemorrhage with hemosiderosis, scars of infarcts, and papillary necrosis.<sup>10,46,81,252,337</sup> In addition, abnormalities of the glomerular basement membrane with or without glomerular fibrosis as well as anatomic changes similar to those of proliferative glomerular nephritis have been described.

The *liver* usually is enlarged and the lesions include engorgement of the sinusoids with sickled erythrocytes, hemosiderosis, and enlarged Kupfer cells with red cell phagocytosis.<sup>271</sup> Massive infarction of the liver has been occasionally encountered and there are varying degrees of cellular infiltration and fibrosis.

The *spleen* is enlarged in childhood and is fibrotic in adulthood. The splenic sinusoids are dilated and the littoral reticuloendothelial cells are hyperplastic. Erythrophagocytosis is prominent and irreversibly sickled cells are present in the sinusoidal spaces. By light and electron microscopy these appear as dense, dark cells. Findings in the spleens of children are similar to those noted in other forms of hemolytic anemia in which red cell entrapment is prominent.<sup>78,327</sup>

### Management and Therapy

Because the natural course of sickle cell anemia has never been comprehensively documented, the long-term results of many therapeutic manipulations cannot be adequately

evaluated. Many medications and manipulations have been touted as beneficial, only to be found ineffective or even deleterious to health upon prolonged or more careful study. Programs directed at the education of groups of laymen as well as patients, together with adequate screening and genetic counseling, may be expected to have an impact on the management of the sickle cell disorders.<sup>119,314</sup> The identification of adult persons with sickle cell trait will permit informed decisions to be made about family planning. Recognition of sickle cell disease at the time of birth may allow the prevention of some of the complications and catastrophes that occur in early childhood.<sup>53</sup> The psychosocial aspects of management are complicated and multifactorial; although of great importance, they are not susceptible to simple guidelines.<sup>350a</sup> Many patients are physically active and lead nearly "normal" lives during their earlier years, except when specific and serious complicating illnesses, such as pneumonia or splenic sequestration, occur or painful sickle cell crises develop. The diagnosis of sickle cell crisis requires exclusion of the possibility of other disease, as discussed earlier (page 829), and identification of precipitating causes. Many medications have been used, but no single nonanalgesic, noncontroversial agent has been described.

### Blood Transfusion

The single, least controversial, and most effective therapeutic measure available is the transfusion of normal red cells. Repeated transfusions, or repeated partial exchange transfusion therapy, has been advocated and has been effective in the prevention of painful episodes and in the enhancement of growth.<sup>32,33,315</sup> Transfusion probably is of benefit in the management of splenic sequestration, priapism, renal epistaxis, surgical procedures, and cardiovascular and other life-threatening complications. However, repeated transfusion therapy for prophylactic purposes is not a simple matter because of problems in the acquisition of compatible blood, transfusion reactions, and the hazards of hepatitis and iron overload. For these rea-

sons, transfusions are best reserved for the more severe episodes of clinical illness or for patients who have severe disease and almost constantly recurrent symptoms. Exchange transfusions may provide the advantages over single transfusion in that smaller increases of blood volume, minimal additions to iron overload, and perhaps greater numerical gain in the ratio of normal cells to sickle cells are produced.

### Other Approaches to the Treatment of Sickle Cell Crises

Since painful episodes are precipitated by infection, fever, dehydration, acidosis, and perhaps by cold as well,<sup>273a</sup> measures that prevent or remedy these conditions have been used. Hydration is essential; induction of alkalosis has been stated to be of benefit by some<sup>15,116</sup> but others have refuted this claim.<sup>269</sup> Carbonic acid anhydrase inhibitors have been used with the expectation of decreasing intracellular carbonic acid, but such treatment has not been of clinical benefit.<sup>99</sup>

The pharmacologic approach to the treatment of painful crises has included attempts to modify HbS chemically in order to minimize hemoglobin molecular polymerization and its consequences. Conversion to methemoglobin of a part of the HbS by oral administration of nitrates has not been particularly helpful.<sup>32</sup> Attempts to affect sol-gel transformation at the hemoglobin-membrane interface and to alter the cell membrane have included the use of phenothiazines,<sup>130,207,235</sup> progesterones,<sup>146</sup> testosterone,<sup>210</sup> and other steroidal hormones.<sup>2</sup> Clinical trials<sup>130,146,210,233</sup> give conflicting impressions regarding their efficacy. Magnesium sulfate,<sup>15</sup> hyperbaric oxygen,<sup>76,182,263</sup> and dextrans,<sup>14,103,234,340</sup> have been used, but are not clearly beneficial. Attempts to minimize cell aggregation and vascular thrombosis with dextrans,<sup>14,103,234,340</sup> with anticoagulants,<sup>170,264,280</sup> and with agents that deplete coagulation proteins (Arvin)<sup>106</sup> have been made, but none of these has proven value and their use over prolonged periods carries significant risks. HbS cells treated with nitrogen mustard have decreased propensity to sickle and have

normal oxygen association characteristics.<sup>272</sup> However, the concentration of nitrogen mustard needed to inhibit sickling precludes its *in vivo* use.<sup>53</sup>

Orally administered urea has been advocated for the prevention of painful episodes and intravenously administered urea, for the alleviation of pain and the prolongation of cell survival.<sup>204,205</sup> The rationale for urea therapy was based on the hypothesis that hemoglobin polymerization depends on intramolecular hydrophobic bonding and the fact that urea can disperse such bonds.<sup>227,228</sup> Interference of gelation of deoxy-HbS solutions by urea has been demonstrated,<sup>9</sup> and inhibition of sickling as well as the effects of urea on the oxyhemoglobin dissociation curve have been described.<sup>43</sup> Studies of the *in vitro* effects of urea have shown a decrease in viscosity of deoxy-HbS solutions and inhibition of the sickling phenomenon by 0.4 M urea (equivalent to BUN of 1120 mg/dl), but not by 0.1 M urea (equivalent to BUN of 280 mg/dl).<sup>296</sup> These studies have not substantiated claims of *in vitro* inhibition of sickling by much lower concentrations of urea such as 0.01 M (equivalent to BUN of 28 mg/dl).<sup>196,227,228</sup>

Uncontrolled preliminary clinical studies showed conflicting results, with benefit in some<sup>206,227,228</sup> but not in others.<sup>192,195</sup> A clinical cooperative controlled study of the effect of the intravenous administration of urea in invert sugar demonstrated no benefit from urea as compared with alkali or with simple hydration.<sup>177</sup> Because of these studies, most investigators believe that urea is not a therapeutically valuable agent. Moreover, administration of urea may be associated with accelerated hemolysis,<sup>25,192</sup> and may produce a potentially dangerous diuresis.

Potassium cyanate inhibits sickling by different mechanisms than that proposed for urea.<sup>50,51,74,77,178,198,201</sup> One mechanism is the specific inhibition of polymerization as the result of carbamylation of the N-terminal group of the hemoglobin polypeptide. Perhaps a more important effect is an increase in the oxygen affinity of the carbamylated hemoglobin. Because of the increased oxygen affinity, there is less deoxy-HbS at a given

oxygen tension and less propensity for sickling.<sup>215</sup>

HbS cells have been treated *in vitro* with cyanates<sup>107,152,180,216</sup> and have shown prolonged survival upon reinfusion. Patients treated with oral sodium cyanate in amounts of 20 to 30 mg/kg/day have been found to have increased red cell survival times, but clinical improvement has not been impressive.<sup>53,250</sup> There are insufficient data regarding cyanate therapy to provide estimates of its value or to make suggestions concerning indications for its use. The long- and short-term toxic effects of cyanate at various dose levels, including hepatotoxicity in rats<sup>108,230</sup> and dose-related motor peripheral neuropathy observed in patients and in dogs, require careful evaluation.

Administration of oxygen to patients in crisis offers little if any benefit, but oxygen should be given to patients with ancillary cardiopulmonary disease.

### Treatment of Complications

The complications of sickle cell disease are numerous, and many require surgical care. When general anesthesia is to be used, partial exchange transfusion may be preferable to standard blood transfusions, in order to avoid blood volume overload. There is no evidence

that high hemoglobin concentrations improve the healing process.<sup>53</sup> Furthermore, the dangers of cardiac failure or pulmonary disease during the surgical-anesthetic event are enhanced by an overexpanded blood volume. Transfusions usually are not needed when local or spinal anesthesia is used. When orthopedic operations are performed and tourniquets must be used to maintain hemostasis, exchange transfusions are necessary.

*Ankle ulcers* (Fig. 25-6) are distressing and quite common. They have been classified in various ways and possibly require different types of management.<sup>332</sup> Bed rest, elevation of the affected extremities, and wet-to-dry dressings are initial forms of therapy. Antibiotics should be administered systemically if septicemia or extensive local infections are present. Maintaining a normal Hb level for some months by transfusion and grafting with a fairly thick split-thickness graft may be beneficial.<sup>332</sup> Zinc deficiency has been suggested as contributing to ulceration<sup>301a</sup> and there are reports of beneficial effects of oral therapy with zinc sulfate in patients with venous stasis ulcers and low serum Zn levels.<sup>122a</sup> Occlusive gel boots (Unna boots) are used when the acute inflammation has subsided, and the patient then may assume partial ambulation. Because of the tendency to slow healing and the recurrent nature of the

Fig 25-6. Chronic leg ulcers in a patient with SCA (Courtesy of Dr. A. F. Jonas, Jr.)

leg ulcers, gradual ambulation and the prophylactic use of lightweight support stockings are advisable.

The multiple osseous disorders that occur may require orthopedic surgical procedures. Aseptic necrosis of the hip may be managed without surgical therapy, but in patients with severe disease either arthroplasty or total hip replacement may be necessary.<sup>63,90</sup>

The ocular involvement in SCD may include neovascularization of the retina with retinal tears, and such lesions may require photocoagulation or surgical intervention. Exchange transfusion is usually indicated prior to ocular surgery.<sup>11</sup>

Whether or not all patients with SCD should receive daily supplemental folic acid is uncertain, but evidence of folate deficiency does occur, either with or without demonstrable clinical effects or megaloblastic anemia.<sup>161,194,241,256,341</sup> It seems judicious to give 0.3 mg of folic acid daily, especially to patients who are pregnant or to those who have decreased folic acid sources.

## Hemoglobin C Disorders

### Hemoglobin C

In HbC, lysine replaces glutamic acid in position 6 of the  $\beta$ -chain (Chapter 4, page 174). This abnormal hemoglobin is more stable in reduced form than is normal hemoglobin and is more soluble than HbA. However, under conditions that permit partial drying and partial hemolysis, HbC may crystallize in vitro, provided its concentration is sufficiently great (more than 44%).<sup>57</sup> Thus, tetragonal crystals of hemoglobin were demonstrable when suspensions of washed erythrocytes in 3% sodium citrate solution were sealed under a coverslip, left at room temperature for hours, and allowed to dry slowly. Intraerythrocytic crystals of HbC have been observed in blood smears of individuals with HbC disorders and such red corpuscles may assume a rigid rod-shaped form.<sup>82,84,187</sup> This phenomenon, however, is not unique for HbC and has been reported to occur with a wide variety of other hemoglobinopathies.<sup>187</sup>

The HbC gene is found in 2 to 3% of the

Negro population in the United States. About one in 6000 persons have HbC disease (Table 24-7, page 813). In Africa, the gene distribution is very unusual. There is a 14% gene frequency in Northern Ghana and the Upper Volta, with a rapidly declining incidence in all directions from there.<sup>193,275</sup> However, sporadic instances of HbC trait and even of HbC disease<sup>102</sup> have been reported in individuals in whom African ancestry was improbable.

HbC trait (HbAC) is characteristically an asymptomatic state, with the possible exception of the rare occurrence of hematuria or priapism.<sup>269</sup> Target cells are found in association with HbC trait in various numbers, but anemia is not present and there is no evidence of increased blood destruction. No evidence of gene interaction was observed when HbC trait was found in association with pernicious anemia, glucose 6-phosphate dehydrogenase deficiency, or hereditary elliptocytosis.<sup>312</sup> The HbC trait does not seem to complicate other diseases or make them more severe, except for  $\beta$ -thalassemia minor (page 873) and HbS trait (page 844).

### Homozygous HbC Disease (HbCC)

The usual clinical picture of HbC disease includes mild intermittent abdominal discomfort, occasional arthralgia without overt arthritis, intermittent mild jaundice, splenomegaly, and, occasionally, hematuria in a Negro who otherwise is quite well.<sup>128,163,164,258,312,329,347</sup> The disease usually is discovered when medical attention is sought for unrelated symptoms or during the conduct of a hemoglobin screening program.

The few symptoms of HbC disease are not aggravated by other diseases, except possibly those that cause dehydration and hyperosmolality of the blood, such as diabetic hyperglycemia. These conditions may cause intraerythrocytic dehydration with formation of intraerythrocytic hemoglobin crystals and an increase in the usually minimal rheologic abnormalities of blood flow. Cholelithiasis is said to be more common in individuals with this disease than in normal persons. Unlike sickle cell disease, there is no known in-

Fig. 25-7 Photomicrograph of stained smear from a patient with homozygous C disease (HbCC) showing the characteristic target cells

creased morbidity or mortality associated with pregnancy.

The red cells are strikingly abnormal (Fig 25-7). A mild hemolytic anemia with target cells, microspherocytes, and occasional crystal-containing cells<sup>3,57,84</sup> is associated with decreased erythrocyte cation content, abnormality of cell water,<sup>225</sup> and a tendency to increased intracellular viscosity with decreased cell deformability. The formation of hemoglobin aggregates and of crystals is thought to account for the rigidity of the red cells, their decreased filtrability, and possibly their fragmentation with formation of the dense microspherocytes that are always present.<sup>155,157</sup> In the absence of the spleen, these changes are especially striking. Erythrocyte osmotic fragility curves are abnormal, indicating the presence of populations of excessively fragile cells (microspherocytes) as well as resistant ones (target cells).<sup>159</sup>

Together with a modest shortening of red cell life span, there is constant mild reticulocytosis and normoblastic hyperplasia of the bone marrow. Erythrokinetic studies show increased rates of plasma iron turnover and incorporation of iron into the red cell mass<sup>156,325</sup>—findings consistent with the degree of hemolysis. There is no evidence of increased destruction of cells in the bone marrow and, although the spleen sequesters cells, there is little clinical benefit from splenectomy. There is no distinctive morbid anatomic feature that distinguishes HbC disease

from other varieties of modest chronic hemolytic anemia.<sup>156</sup> Therapy is neither available nor needed. The entity should be recognized in order to avoid unnecessary diagnostic and therapeutic procedures.

### Sickle Cell-Hemoglobin C Disease

Sickle cell-hemoglobin C disease results from the inheritance of a HbS gene from one parent and of a HbC gene from the other parent (Chapter 24). This doubly heterozygous condition is found predominantly in Ghana and in the New World. Among Negroes, the disease has an approximate frequency of 1:833 births in the United States<sup>221</sup> (Table 24-7) and 1:1400 births in Jamaica.<sup>300</sup> In Ghana, the disorder is about as common as sickle cell anemia, and in some regions affects 25% of the population.<sup>174</sup>

The disorder is similar in clinical presentation to SCA, but is of lesser severity and is more compatible with longevity. Several series of patients have been reported—from the United States,<sup>263</sup> Africa,<sup>175</sup> and Jamaica<sup>271</sup>; in these the clinical features were similar but in all there was a wide range of clinical severity.

Growth, body habitus, and sexual development are nearly normal. The cardiovascular changes that are so common in SCA are minimal. In about 40% of the patients in one series<sup>300</sup> the disease was only discovered after its subjects were 20 years of age. The most common complaint is musculoskeletal pain, which is mild to moderate, may be widespread and symmetrical, and may be limited to one portion of the affected bone or bones. The relatively benign course of HbSC disease is attended by several complications that are said to be more common than in SCA. Aseptic necrosis of the femoral heads (Fig. 25-8) has been observed in a high proportion of the patients.<sup>239a</sup> Acute pulmonary disease was found to be common in Jamaica<sup>300</sup> and in the United States.<sup>268</sup> Splenomegaly was present in about two thirds of the adult patients in both series. Symptomatic splenic infarction and the splenic sequestration syndrome occur even in adults. It has been stated that complications of pregnancy are more common

Fig. 25-8. Aseptic necrosis of the femoral heads in a patient with sickle cell hemoglobin C disease. There is irregular erosion of the articular cartilage, erosion of the superior cortical margin of the femoral heads, and a mixture of radiolucency and increased density throughout the femoral heads.

and severe in HbSC disease than in SCA, but the evidence is conflicting (see page 835).

A high incidence of ocular involvement was not emphasized in earlier series, but retinal vascular disease was present in almost all of the Jamaican patients and one third had retinitis proliferans. An analysis of age-matched groups of patients with SCA and sickle cell-hemoglobin C disease revealed that retinal disease was more severe in the latter group.<sup>67</sup>

About 20% of patients with sickle cell-hemoglobin C disease have leg ulcers at one time or another. Hepatomegaly is present in about 40% and clinically detectable jaundice is uncommon, but mild hyperbilirubinemia is frequent. There is usually a modest anemia; only about 10% of the patients have Hb levels less than 10 g/dl. Transient, more severe anemia can develop in the presence of bleeding or infection. The cells are normocytic, normochromic and blood films contain many target cells, but few irreversibly sickled cells. On blood smears and in wet preparations

there are occasional cells that contain condensed hemoglobin crystals that are dark and have parallel sides with a pyramidal or rounded shape<sup>84</sup> (Fig. 25-9). These crystals presumably are formed from both S and C hemoglobin molecules. Although it is not possible to distinguish clearly between the sickled cells of patients with SCA and those with sickle cell-hemoglobin C disease, the latter often form quite characteristic double aggregates within the cell. Reticulocyte counts are only modestly increased, there is normoblastic hyperplasia of the bone marrow, with an increased rate of red cell production and decreased red cell life span.<sup>222</sup>

Although the course of SC disease is benign as compared with that of SCA, occasionally neurologic lesions and episodes of priapism or hematuria occur, in addition to the clinical manifestations previously described. Most of the patients have reasonably good health, however, and the disorder is compatible with long life. The disease may remain undiagnosed, or may be detected dur-

Fig 25-9 Photomicrographs of stained blood smears of patients with HbSC disease. Dark, blunt protuberances and other distortions produced by condensation of hemoglobin crystals are seen. In C the red corpuscle is elongated and the hemoglobin is concentrated at each end, leaving a hemoglobin-free central area. (From Diggs and Bell<sup>22</sup> courtesy of the authors and Grune & Stratton, Inc.)

ing the course of a family study, or during pregnancy.

## Hemoglobin D

Hemoglobin D has the same electrophoretic mobility at alkaline pH on conventional media as does sickle hemoglobin.<sup>199</sup> HbD is distinguished from HbS by agar gel electrophoresis, at pH 6.2, by its normal solubility, and by the fact that it does not cause sickling. Although there are a number of hemoglobins D with  $\beta$ -chain mutations (eg, D Bushman [16 Gly  $\rightarrow$  Arg], D Ibadan [87 Thr  $\rightarrow$  Lys], and D Punjab [121 Glu  $\rightarrow$  Gln], also known as D Los Angeles, Cyprus, Conley, Chicago, Portugal), only D Punjab occurs commonly.<sup>199,276</sup> Alpha-chain abnormalities that

have the electrophoretic mobility of HbD include HbD St Louis and HbD Washington, which are the same as HbG Philadelphia ( $\alpha_2^{65} \text{Asn} \rightarrow \text{Lys}$ ). These hemoglobins cannot be separated, one from another, by electrophoresis. HbD Punjab probably arose in India, and is found among American Negroes about once in 2500 individuals.<sup>276</sup> Persons with HbD are usually found by means of screening examinations and, without electrophoresis at acid pH, sickling tests, or solubility tests, they would be mistaken for persons with the sickle cell trait. Except for hematuria, no clinical, hematologic, or physiologic abnormalities are associated with the hemoglobin D trait (HbAD).<sup>119</sup> Homozygous HbD disease is rare. It may be associated with mild hemolytic anemia, but there are virtually no

symptoms. There is no splenomegaly, but target cells and spherocytes are found.<sup>324</sup>

### Sickle Cell-Hemoglobin D Disease

Sickle cell hemoglobin D disease is uncommon.<sup>148,311</sup> It is clinically indistinguishable from the more mild cases of SCA. HbS and HbD interact and produce hemoglobin polymerization, the sickling phenomenon, and the previously described findings of SCA.<sup>49,267,285</sup> Since these patients have sickled erythrocytes and hemoglobin that migrates in the HbS position at pH 8.6, they may be misdiagnosed as having SCA. The clinical characteristics are not uniform, but all the subjects have hemolytic anemia. Some patients have had severe disease and others were almost asymptomatic.<sup>321</sup>

HbD is easily separated from HbS by agar gel electrophoresis at pH 6.2. HbD-thalassemia with clinical disease resembling SD disease was reported in a Persian girl<sup>143</sup> as well as in a family with  $\beta$  thalassemia-HbD.<sup>163</sup>

## Hemoglobin E

Hemoglobin E has an electrophoretic mobility slightly anodal to HbC at pH 8.6 and is about equal in solubility to HbA. The abnormality results from the substitution of lysine for glutamic acid at the 26th amino acid of the  $\beta$ -polypeptide chain (Table 24-1). HbE is found in a high proportion of Thais, (13.6%),<sup>60</sup> in Burmese (15.3%),<sup>64</sup> in Cambodians (35%),<sup>45</sup> and in some Indonesian, Ceylonese, and Malaysian (1%) populations. Significantly higher frequencies have been observed in highly malarious areas of Thailand than in neighboring regions where there is a low incidence of malaria.<sup>100</sup> Elsewhere than in Asia, occasional cases have been encountered.<sup>5,335a</sup> HbE<sub>Saskatoon</sub> ( $\beta^{226} \text{Glu} \rightarrow \text{Lys}$ ) has been reported in individuals of Scottish origin.<sup>335a</sup>

The heterozygous abnormality, HbE trait (HbAE), is asymptomatic. There is no sickling, minimal hypochromia, no target cells, and there are no inclusion bodies or alterations of osmotic fragility. About 35 to 49%

of the hemoglobin is HbE, the remainder being HbA.<sup>338</sup>

### Homozygous HbE (EE) Disease

The homozygous state (HbEE) is quite common among Asiatic populations and is characterized by a mild microcytic, normocytic anemia with 25 to 60% target cells, decreased osmotic fragility, and minimal signs of hemolytic anemia. Splenomegaly is absent or slight. Approximately 92 to 98% of the hemoglobin in the erythrocytes is HbE. The quantity of HbF is normal or slightly increased.<sup>60,190a</sup> HbC disease and HbE disease may be difficult to distinguish one from the other, but, in addition to the racial differences of the subjects, usually more target cells are present and splenomegaly is more pronounced in persons with HbC disease than in those with HbE disease. HbE can be distinguished from HbC by acid agar gel electrophoresis and by various chromatographic techniques, or by "fingerprinting" (Chapter 24).

## HbS-O Arabia

The substitution of HbO Arabia ( $\beta^{121} \text{Glu} \rightarrow \text{Lys}$ ) causes a charge difference which is similar to that of HbC. On routine electrophoresis this hemoglobin migrates to that position.

Patients with HbS and HbO Arabia have been reported from the Sudan,<sup>144,257</sup> the United States,<sup>150</sup> and Jamaica.<sup>217</sup> The clinical manifestations are such that, on routine examination and electrophoresis, they would easily be mistaken for those of hemoglobin SC disease.

Diagnosis and Differential Diagnosis of Thalassemia

The early observations regarding the beginnings of molecular biology, and their relation to the hemoglobinopathies and thalassemia, were briefly alluded to in Chapter 24. Even before homozygous and heterozygous forms of thalassemia were recognized, observers<sup>98,146</sup> noted considerable variation in the manifestations and severity of the disease; thus, terms such as "thalassemia intermedia" and "thalassemia major," to represent the clinically severe homozygous state, and "thalassemia minor" and "thalassemia minima," to refer to the considerably milder, heterozygous form, were introduced. It is now recognized that thalassemia comprises a heterogeneous group of inherited disorders of hemoglobin synthesis. Indeed, it can no longer be said that the presence of hypochromic, microcytic red corpuscles which are not the result of iron deficiency and whose osmotic fragility is decreased is the *sine qua non* of thalassemia. The morphologic picture varies in the different thalassemia syndromes, even to the point of total absence of abnormal

morphologic features or clinical manifestations in some heterozygotes.

The one common denominator of all the thalassemia syndromes is a decreased rate of synthesis of one or more hemoglobin polypeptide chains.<sup>50</sup> This primary feature is a quantitative one and contrasts with the qualitative changes in hemoglobin structure that characterize the hemoglobinopathies. Included under the category of thalassemia are all the inherited varieties of quantitative impairment of production of the normally occurring fractions of adult hemoglobin, as

well as persistence into adult life of fetal hemoglobin, and the Lepore hemoglobins, which are produced by unequal crossing over between the  $\delta$ - and  $\beta$ -genetic structural loci.

The thalassemia syndromes are classified according to the polypeptide chain or chains involved and will be described under those headings.

The clinician, confronted by the long list of possible forms of thalassemia presented in Table 26-1, may be taken aback. Fortunately, he need not be. His task is to determine whether he is dealing with one of the thalas-

Table 26-1. Classification of  $\beta$ - and ( $\delta\beta$ )-Thalassemias

Genotype	Clinical	Hemoglobin Pattern			
		Hb A <sub>2</sub> %	Hb F %	Hb A %	Other Hemoglobins
$\delta\beta$ $\delta\beta$	Normal	2.5-3.0	0	97	none
<i>Heterozygous <math>\beta</math> chain defects</i>					
(1) $\delta\beta$ $\delta^{\text{thal}}\beta$	Nil	Low	0	100	0
(2) $\delta\beta$ $\delta^{\text{fthal}}\beta$	Nil	2.5-3.0	0	>90	0
(3) $\delta\beta$ $\delta\beta^{\text{thal}}$	Thalassemia minor	3.5-7.5	1-5	>90	0
(4) $\delta\beta$ $\delta\beta^{\text{fthal}}$	Thalassemia minor	3.5-7.5	SI inc in some	94	0
(5) $\delta\beta$ ( $\delta\beta$ ) <sup>thal</sup>	Thalassemia minor	2.5-3.0	5-20	<80	0
(6) $\delta\beta$ ( $\delta\beta$ ) <sup>Lepore</sup>	Thalassemia minor	1.2-2.6	1.3-14	+	Lepore 6-15%
<i>Homozygous <math>\beta</math> chain defects</i>					
(7) $\delta\beta^{\text{thal}}$ $\delta\beta^{\text{thal}}$	Thalassemia intermedia	SI inc	6-12	>85	0
(8) $\delta\beta^{\text{thal}}$ $\delta\beta^{\text{fthal}}$	Cooley's anemia† or intermedia	Variable	20-80	+	Free alpha chains
(9) $\delta\beta^{\text{thal}}$ $\delta\beta^{\text{fthal}}$	Cooley's anemia	Variable	Almost all	0	Free alpha chains
(10) $\delta\beta^{\text{thal}}$ ( $\delta\beta$ ) <sup>thal</sup>	Thalassemia intermedia (mild)	1	60-99	0 or +	0
(11) ( $\delta\beta$ ) <sup>thal</sup> ( $\delta\beta$ ) <sup>thal</sup>	Thalassemia intermedia†	0	100	0	0
(12) ( $\delta\beta$ ) <sup>Lepore</sup> ( $\delta\beta$ ) <sup>Lepore</sup>	Cooley's anemia	0	75	0	Lepore
<i>Doubly heterozygous <math>\beta</math> chain defects</i>					
(13) $\delta\beta^{\text{thal}}$ $\delta\beta^{\text{fthal}}$	Similar to sickle cell anemia§ but usually milder	inc	10	20	70% S
(14) $\delta\beta^{\text{thal}}$ $\delta\beta^{\text{fthal}}$	Similar to sickle cell anemia§	inc	10	0	90% S
(15) $\delta\beta^{\text{thal}}$ ( $\delta\beta$ ) <sup>thal</sup>	Similar to sickle cell anemia§ but usually milder	+	+	0	S

$\beta$  refers to the normal gene for  $\beta$  chain synthesis,  $\delta$  to the normal gene for  $\delta$ -chain synthesis,  $\beta^{\text{thal}}$  to the  $\beta$  thalassemia gene with some  $\beta$ -chain production,  $\beta^{\text{fthal}}$  to the  $\beta$  thalassemia gene with no  $\beta$ -chain production ( $\delta\beta$ ) indicates that both  $\delta$ - and  $\beta$ -chain synthesis are affected

\* Silent  $\beta$  thalassemia gene

§ Sickle cell thalassemia

|| In the hemoglobin pattern columns + means present

semia syndromes, rather than iron-deficiency anemia, one of the hemoglobinopathies, or another condition from which thalassemia must be distinguished, as discussed on page 883. In general, heterozygous inheritance of a thalassemia gene produces thalassemia minor or minima, or no clinical manifestations at all, while homozygous or doubly heterozygous thalassemia produces Cooley's anemia or thalassemia intermedia. From a practical, clinical standpoint it is not necessary for the clinician to identify the genotype of his patient in accordance with the lists given in Tables 26-1 and 26-3. He can and should carry out family studies in order to identify other members of the family who have anemia, splenomegaly, or other features attributable to thalassemia. This will avoid confusion at later times. Family studies, however, can be carried out by relatively simple means. More specific identification of the genotype is a task for the specialized laboratory.

### Genetic Mechanisms Resulting in Thalassemia

The present widely accepted concept of the genetic mechanisms that result in thalassemia is derived in part from genetic studies, especially of individuals doubly heterozygous for thalassemia and one of the abnormal hemoglobins, such as Hb S, and also from the application of simple and reliable methods for the separation and isolation of the globin chains of hemoglobin. The latter methods have made possible measurement of the in vitro rate of globin chain production in reticulocytes of patients with different forms of thalassemia.

It was observed, for example, that in individuals heterozygous for the  $\beta$ -thalassemia gene and for Hb S, the Hb S level was 58 to 94%, in contrast to the 25 to 47% usually found in carriers of the Hb S trait.<sup>53</sup> This was interpreted as indicating that the  $\beta^{\text{thal}}$  mutation selectively suppressed the synthesis of  $\beta$ -chains directed by that locus, whereas the other, (trans)  $\beta^S$ , gene had not been inhibited. The term "interaction" is used to describe the reversal of the normal hemoglobin A/S ratio which occurs when the  $\beta$ -thalassemia gene is

found in association with the sickle cell gene.

Unbalanced synthesis of the globin chains has been demonstrated in peripheral blood reticulocytes by measurement of the incorporation of radioactive amino acids into the globin chains.<sup>2</sup> In homozygous  $\beta$ -thalassemia, the  $\beta/\alpha$ -incorporation ratio was found to be less than 0.2; in the heterozygous state, 0.5; and in normal subjects, 1.0<sup>33,34</sup> (Fig. 26-1). There have been conflicting reports regarding  $\beta/\alpha$  synthetic ratios in the erythroid precursors of the red corpuscles in bone marrow in  $\beta$ -thalassemia, ranging from equal synthetic ratios in the heterozygote cells<sup>30,46</sup> to marked imbalance in the homozygote.<sup>48</sup> The reported discrepancies have been explained in various ways<sup>9,38</sup> and obviously deserve further investigation. Imbalance between  $\alpha$ - and  $\beta$ -chain synthesis also has been described in Hb H disease and between  $\alpha/\gamma$ -chain synthesis in homozygous ( $\delta\beta$ )-thalassemia.<sup>48</sup>

In the majority of patients with thalassemia the quantity of  $\beta$ -polypeptide chain ( $\beta^{\text{thal}}$ ) or  $\alpha$ -chain ( $\alpha^{\text{thal}}$ ) is reduced, but the amino acid sequence of the chain is normal. In some subjects there is even complete absence of gene product; that is, one of the polypeptide chains is totally lacking.<sup>57</sup> However, in the Lepore hemoglobins the polypeptide chain is abnormal, but this is merely in the sense that it represents a fusion of otherwise normal parts of the  $\delta$ - and  $\beta$ -polypeptides to form a chain of normal length. Structural abnormalities are also found in Hb Constant Spring (page 881).

An early finding was the fact that, in the total or partial absence of the  $\beta$ -peptide chain, the amount of  $\delta$ -chain or  $\gamma$ -chain is increased with increased levels of Hb A<sub>2</sub> or Hb F. This observation has proved helpful both in classifying the different forms of  $\beta$ -thalassemia and also in the recognition of many thalassemia syndromes. In the  $\alpha$ -thalassemias, a different situation obtains (page 876).

The logical conclusion to be drawn from observations such as those described above is that thalassemia is the result of a breakdown of the mechanisms that are concerned

Fig 26-1. Beta/alpha synthetic ratios in various forms of thalassemia after incubation of peripheral blood with leucine- $U^{14}C$ .

The cells were incubated for two hours in autologous plasma in the presence of the labeled amino acid. The globin chains were isolated by urea-CMC chromatography. The specific radioactivity of the chains and the ratios of their radioactivity were then determined (From Nathan,<sup>14</sup> courtesy of the author and the New England Journal of Medicine.)

with normal globin-chain production.<sup>62</sup> This intricate process involves initiation of globin-chain synthesis, turning off  $\epsilon$ - and  $\gamma$ -loci and activating the  $\beta$ - and  $\delta$ -loci during the early developmental stage, synchronization of  $\alpha$ -chain synthesis with that of the other globin chains, maintaining  $\delta$ -chain synthesis at about 2.5% of that of  $\beta$ -chain production, and stopping globin production when the erythrocyte has been furnished a full complement of hemoglobin. In addition, heme synthesis must be coordinated with globin synthesis. Unfortunately, most of these activities occur in the nucleated red cell, rather than in the reticulocyte, which is the most available structure for *in vitro* studies.

Investigation has been hampered because so little is known about control mechanisms at the chromosomal level in man, as compared with models derived from microbial systems. To what extent the operon hypothesis<sup>29</sup> can account for the regulation of protein synthesis in mammalian cells is unknown, nor is the significance of the high DNA content of the cell nuclei of higher organisms in relation to protein synthesis understood.<sup>56</sup> Somewhat less obscure is the subject of globin-chain production during assembly on the polyosomes.

Sufficient has been learned about the genetic basis of thalassemia, however, to rule out a defect in heme synthesis,<sup>9</sup> or a "silent" amino acid substitution, that is, one that fails to produce an electrophoretically abnormal hemoglobin.<sup>26,27</sup> Possibilities that have not

been entirely excluded include deletion of the  $\beta$ -gene in those instances of  $\beta$ -thalassemia in which no  $\beta$ -chains are synthesized, mutations resulting in the formation of codons that dictate chain termination (eg, "amber" and "ochre"),<sup>18</sup> or the development of a mutation that would call for a different, less available transfer RNA (tRNA) to read a given codon, with resulting slowing of the rate of translation of a given messenger RNA (mRNA).<sup>28</sup> However, in most cases, neither initiation<sup>10a,19,41</sup> nor translation<sup>9,43,45</sup> has been found defective. An exception may be represented by Ferrara  $\beta$ -thalassemia<sup>153</sup> where it was found that addition of ribosome and mRNA-free supernatants from nonthalassemic subjects induced globin synthesis in thalassemic ribosomes, thereby suggesting mutation of a gene coding for a factor necessary for  $\beta$ -globin mRNA translation.

As far as most of the  $\beta$ -thalassemias are concerned, best supported is the hypothesis that the fault lies in transcription, leading to a reduced amount of normal  $\beta$  mRNA.<sup>1a,6,15,29a,41,42,46</sup> The same seems to be true of the  $\alpha$ -thalassemias.<sup>15,22</sup> Thus, mRNA isolated from reticulocytes of  $\beta$ -thalassemia directed synthesis of normal  $\alpha$ - or  $\beta$ -chains, but the amount of  $\beta$ -chains synthesized was markedly reduced. In contrast, mRNA isolated from the reticulocytes of normal blood, or sickle cell blood, directed synthesis of normal  $\alpha$ - and  $\beta$ -chains and normal  $\alpha$ - and  $\beta^S$ -chains, respectively, in normal amounts.<sup>6</sup>

The mode of inheritance of the thalassemia

disorders is consistent with the view that they are the result of autosomal (non-sex-linked) gene mutations. The genetics of the  $\alpha$ -thalassemias has been particularly difficult to fathom, as will be discussed in a later section of this chapter (page 881).

The  $\beta$ -thalassemia genes appear to be allelic or closely linked with the genes for amino-acid substitutions affecting the  $\beta$ -chains. Likewise, the  $\alpha$ -thalassemia genes are allelic or closely linked with  $\alpha$ -chain hemoglobinopathies. The  $\beta$ - and  $\alpha$ -genes occupy widely separated loci, probably on separate chromosomes (Chapter 24).

The phenomenon of interaction was mentioned above in regard to interaction between the  $\beta$ -thalassemia and Hb S genes. Similarly, interaction has been observed between  $\alpha$ -thalassemia and  $\alpha$ -structural gene mutations.<sup>268,275</sup> However, no similar interaction occurs between  $\alpha$ -thalassemia and  $\beta$ -structural gene mutations.<sup>27</sup>

### Pathologic Physiology

From the pathophysiologic standpoint, the central features of thalassemia are: (1) deficient hemoglobin synthesis resulting from deficient production of one or another of the polypeptide chains of globin and (2) accumulation of unused normal chains. The consequences are: (1) precipitation of the free polypeptide chains in the red corpuscles to form inclusion bodies, (2) red cell membrane damage, (3) shortened red cell survival, and (4) the kinetic picture of ineffective erythropoiesis. When the magnitude of the erythropoietic defect is sufficiently great, the consequences are anemia, attempted compensation by increasing and accelerating erythropoiesis, increased activity of the reticuloendothelial system (RES) because of the need to remove the products of corpuscular breakdown, and, ultimately, the accumulation in the tissues of large deposits of iron.

The most striking changes are seen in homozygous  $\beta$ -thalassemia (Cooley's anemia) and in homozygous  $\alpha$ -thalassemia. The latter results in hydrops fetalis. A review of the main findings at autopsy of patients with

Cooley's anemia provides a picture of the ultimate effects of this disease as time is allowed for their evolution.<sup>59</sup> These include evidences of anemia and of active blood formation, both medullary and extramedullary, splenomegaly, striking changes in the bones, and pigmentation of various organs resembling that of hemochromatosis.

The spleen is much enlarged and may show infarcts and adhesions. It is firm and hard. There are foci of extramedullary blood formation, with nucleated red cells, myelocytes, and megakaryocytes.<sup>66</sup> In other areas an increase of stroma and accumulations of foam cells are seen (Fig. 26-2). The foam cells give at best a faint pink color with fat stains, but they give an intense reaction with the periodic acid-Schiff (PAS) stain.<sup>47</sup> Gaucher or Gaucher-like cells have been described, in the bone marrow as well as the spleen. These have been attributed to increased catabolism of erythrocytes giving rise to increased glucocerebroside.<sup>110</sup> The Malpighian corpuscles of the spleen are approximately normal, or small.<sup>59</sup>

The bones may be greatly thickened and the long bones tend to be rectangular in shape. There is atrophy of the bone shafts and trabeculae and, at the same time, proliferation of delicate new bone. In the skull the proliferation is arranged in a more or less parallel, centrifugal pattern (Fig. 26-3).

The bone marrow is hyperplastic and contains many primitive cells, numerous nucleated red cells, and many myelocytes as well as megakaryocytes. There may be a number of macrophages, some containing small amounts of hemosiderin. Foam cells like those described in the spleen may be present in small islands. A PAS-positive substance (Chapter 1, page 29), probably unused glycogen,<sup>44</sup> has been demonstrated in the marrow normoblasts.<sup>1,21</sup>

Iron<sup>59</sup> is abundant in the parenchymal and Kupffer cells of the liver, and in lymph nodes, gastric mucosa, thyroid and adrenal glands, and is usually demonstrable in Brunner's glands, the salivary and mucous glands, the parathyroid glands, hypophysis, heart muscle, and kidney tubules. In children re-

Fig. 28-2 Photomicrograph of spleen from a patient with Mediterranean anemia (thalassemia major) showing nests of foam cells in the pulp and thickened sinusoids (X200) (From Whipple and Bradford<sup>107</sup> courtesy of the authors and American Journal of Diseases of Children)

quiring regular transfusions and surviving to the ages of 8½ to 14 years, a characteristic cirrhosis, as well as myocardial degeneration and right ventricular hypertrophy, was found to be invariable and pericarditis was frequent.<sup>60</sup> The spleen shows only a moderate amount of iron within the reticuloendothelial cells and the skin contains small amounts.

It is plausible to assume that continuous marrow hyperplasia from early life causes the bone changes that are so characteristic of classical Cooley's anemia. The splenomegaly is due to extramedullary hematopoiesis<sup>66,94</sup> as well as to hyperactivity of the RES, as is the hepatomegaly. To these more specific effects can be added the consequences of chronic anemia, including impaired growth and other hormonal<sup>85,89</sup> effects. The severity of all of these changes depends on the degree of impairment in the production of hemoglobin.

The red corpuscles one sees in the blood in Cooley's anemia have the appearance of having been formed with an adequate or excessive membrane but with little hemoglobin. Their extreme thinness accounts for some of

the bizarre forms observed, including the "target" cells. Electron microscopy has shown alterations in surface texture<sup>23</sup> and gross distortion and deformity of the cells. Indentations and infolding of the plasma membrane with vacuole formation are prominent.<sup>95</sup> Intracellularly, a wide spectrum of abnormalities is found, especially in the blood of splenectomized subjects.<sup>95</sup> These include accumulations of iron in different forms within membrane-bound particles or mitochondria, and Heinz bodies in various stages of development.

Cells of patients with thalassemia major are excessively permeable to cations; cation flux is increased and there may be net loss of intracellular  $K^+$ .<sup>39,40</sup> Thalassemia minor red cells show an increase in permeability to  $K^+$ , with consequent loss of cellular  $K^+$ , but there is no change in  $Na^+$  permeability nor an increase in cellular  $Na^+$ . The increased resistance to osmotic lysis characteristic of these cells has been attributed to the water loss associated with the decreased cation content and concomitant shrinkage of the cells.<sup>23</sup>

In  $\beta$ -thalassemia, the deficit in  $\beta$ -chain synthesis results in the production of an intracellular pool of excess  $\alpha$ -chains.<sup>37,54,61</sup> The excess  $\alpha$ -chains are released into the soluble fraction of the red cell and some combine with newly made  $\beta$ - and  $\gamma$ -chains. The remainder, being unstable, rapidly precipitate and become associated with cell membrane. The rapid rate of  $\alpha$ -chain precipitation in  $\beta$ -thalassemia may be the result of hemichrome formation.<sup>44</sup> Heme has been found to be attached to some of the excess  $\alpha$ -chains in the red cells, and the excess of dipyrroles which has been described in thalassemic urine<sup>33</sup> probably reflects breakdown of excess  $\alpha$ -chains with heme attached. The excess of "early-labeled" bilirubin that accompanies the ineffective erythropoiesis<sup>14</sup> probably is derived from the intramedullary destruction of the defective red cells.

The precipitated chains form the inclusion bodies described in the marrow erythroblasts and in the circulating red corpuscles of splenectomized patients.<sup>12</sup> The alterations in membrane structure and function described above are thought to be the consequence of damage associated with inclusion body formation. These insoluble and rigid  $\alpha$ -chain precipitates probably cause fragmentation and

pitting in any area of restricted passage in the microcirculation, thereby giving rise to small, distorted cells.<sup>49</sup> Shortening of red cell survival has been found to be related directly to the degree of chain imbalance in both homozygous and heterozygous  $\beta$ -thalassemia.<sup>32,59</sup> Corpuscles containing inclusion bodies are scarce in the blood of non-splenectomized individuals, no doubt because of the pitting and scavenging activities of the spleen (Chapter 8).

The survival of red cells transfused from subjects with thalassemia major into normal individuals was found to be shortened.<sup>31</sup> It was noted that between 25 and 50% of the cells in thalassemia major blood disappeared from the recipient's circulation in 20 to 30 days, whereas the remainder followed the normal rate of elimination. The survival of red corpuscles from subjects with thalassemia minor who had no icterus was normal.<sup>7,24,31</sup>

Studies of the morphologic characteristics of bone marrow and of iron and porphyrin metabolism indicated that large quantities of heme,  $\alpha$ -chains, and red cells are produced in homozygous  $\beta$ -thalassemia.<sup>21,51</sup> Yet delivery of erythrocytes to the blood is markedly decreased<sup>11</sup> and there is quite extensive premature destruction of red cells in the marrow

Fig 26-3. Coronal section of the calvarium, a rib and costochondral junction, vertebrae and cross section of the shaft of the femur. Case of Mediterranean anemia (From Whipple and Bradford<sup>167</sup> courtesy of the authors and American Journal of Diseases of Children)

(ineffective erythropoiesis),<sup>14</sup> as mentioned above. That there probably are two populations of red cells, one short-lived and the other with a much longer mean survival time, is suggested by the observation that the turnover rate of Hb A, as measured *in vivo* by labeling with [2-<sup>14</sup>C] glycine, is considerably higher than that of Hb F.<sup>18</sup> Differential centrifugation of blood cells revealed that the young cells contained a much higher proportion of Hb A than did older cells. The latter contained relatively more Hb F.<sup>31,39</sup> When the blood of splenectomized patients was examined it was found that the younger cells contained more inclusion bodies than did the older ones. Other differences included a lower hemoglobin content, more distortion, more rapid rate of flux of potassium across the membrane, and a higher rate of glycolysis and lactate formation with low and unstable levels of ATP in younger cells.<sup>33,31,39</sup>

To explain the increased quantities of Hb F in the red corpuscles it has been suggested that, under normal circumstances of erythropoiesis, among the early precursor erythroid cells there are cells that form  $\beta$ - or  $\gamma$ -chains or both. As these cells mature, their ribosomes lose the capacity for  $\gamma$ -chain synthesis when these cells have made only 1 to 2% of their final complement of hemoglobin. Under conditions of erythropoietic stress, erythroid cell maturation is so altered that circulating reticulocytes are derived directly from early erythroid forms that have not lost the capacity to form  $\gamma$ -chains and consequently a greater fraction of Hb F is produced.<sup>8</sup> If, in addition to the accelerated maturation, there is a defect in  $\beta$ -chain synthesis, as in many thalassemia syndromes, the result would be an even greater increase in the proportion of Hb F.

Although, as indicated earlier, a defect in heme synthesis cannot be regarded as a fundamental abnormality in thalassemia, heme synthesis is nevertheless impaired. Thus, *in vitro* studies of thalassemic red blood cells revealed defective utilization of glycine to form  $\delta$ -aminolevulinic acid (ALA). The biosynthetic step between ALA and heme appeared to be intact, but another step, that

following the formation of protoporphyrin or heme, was defective.<sup>53</sup> It was noted that thalassemic hemolysates tended to synthesize a greater percentage of protoporphyrin than did nonthalassemic erythrocytes. This suggests a block in hemoglobin synthesis following the formation of protoporphyrin or heme. It was suggested that, since ALA synthetase is the rate-limiting enzyme in the heme pathway, it is possible that, due to the defect in globin production, heme intermediates accumulate and depress ALA synthetase activity by negative feedback inhibition.<sup>3</sup> That these defects in heme synthesis may, at least in part, be explained by the excess content of iron in the tissues is suggested by the observation in one patient that enzyme activity increased following 4½ months' treatment with desferrioxamine.<sup>50</sup>

As to the manifestations of forms of thalassemia other than classical Cooley's anemia, it is plausible to presume that the remarkable heterogeneity of the thalassemias depends on the degree of chain imbalance, the relative efficiency with which free polypeptide chains are removed, and the quantity of other chains, such as  $\gamma$ -chains, with resulting production of Hb F that is produced. The degree of hypochromia associated with the various forms of thalassemia reflects the severity of the defect in globin-chain synthesis. Thus, hypochromia is not associated with  $\delta$ -thalassemia, in which only the minor  $\delta$ -chain is deficient, or with hereditary persistence of fetal hemoglobin, in which total hemoglobin synthesis is normal.

### $\beta$ - and ( $\delta\beta$ )-Thalassemias

As the result of measurements of Hb A<sub>2</sub> and Hb F, and genetic studies and measurements of the synthesis of  $\beta$ -chains, it has been shown that there are several types of genes that restrict  $\beta$ -chain synthesis and that these lead to clinical forms of thalassemia that differ in severity. The most injurious  $\beta$ -thalassemia gene ( $\beta^{\text{thal}}$ ), found especially in Mediterranean populations, results in the total absence of gene product in homozygotes. A less severe impairment of  $\beta$ -chain

synthesis is associated with a gene designated  $\beta^{\text{thal}}$ . Mildest of all is the so-called "silent" gene ( $\beta^{\text{thal}}$ ). In the heterozygous state, the "silent" gene produces no clinical, hematologic, or hemoglobin electrophoretic abnormalities, but presumably is associated with a mild deficiency of  $\beta$ -chain synthesis. Its presence is inferred when one parent of a child with thalassemia intermedia has typical  $\beta$ -thalassemia trait, whereas the other is "normal." On incubation of the normal parent's red cells with radioactive leucine, a reduced rate of  $\beta$ -chain synthesis was demonstrated.<sup>162</sup>

Still another gene (or genes) affects the synthesis of both  $\delta$ - and  $\beta$ -chains ( $(\delta\beta)^{\text{thal}}$  or  $(\delta\beta)^{\text{thal}}$ ). Finally, a family of  $\delta\beta$  "fusion genes" resulting from unequal crossing-over has been recognized; these genes produce the hemoglobin Lepore syndromes. The effects of these genes and of their combination are summarized in part in Table 26-1.

A variety of terms has been used to describe the different thalassemia syndromes which may be encountered. Unfortunately, some of these terms have been used in a way to imply genetic meanings, leading to a somewhat confused mixture of genetic and clinical terminology. The clinical terms are useful, however, for it often is impossible to define the genetic constitution of an individual with precision. Nevertheless, they should be used only as such. The severest form of  $\beta$ -thalassemia, *thalassemia major* or *Cooley's anemia*, is characterized by marked anemia from infancy, often in the range of 4 to 6 g/dl. A less severe illness has been called *thalassemia intermedia* or "mild Cooley's anemia." This implies more moderate anemia and jaundice, and the subjects may survive into adult life even without blood transfusion. *Thalassemia minor* is an asymptomatic illness, with mild or no anemia, but with prominent morphologic abnormalities of the erythrocytes. Finally, *thalassemia minima* refers to a condition which is undetectable with any certainty except by inference from genetic studies. These various forms of thalassemia will be described and related to genetic constitution in the sections that follow. Their

differentiation from one another and from other hematologic disorders will be discussed at the end of this chapter (page 883) as well as in the individual sections.

### Homozygous $\beta$ -Thalassemia

(*Cooley's Anemia*,<sup>73</sup> *Thalassemia Major*, *High A<sub>2</sub>  $\beta$ -Thalassemia*,  *$\beta$ -Thalassemia Type 1*)

### Clinical Findings

Affected infants fail to thrive. Early in infancy pallor is observed, and there may be a slight degree of icterus. The abdomen enlarges progressively, due to the increasing size of the liver and spleen. Periodic attacks of fever, diarrhea, and a history of poor feeding are common.

When the condition is fully developed, the clinical picture is characteristic. The child is small for its age but the head may appear to be large. The skin is a pale, muddy-yellow and the cheek bones are prominent. This makes the bridge of the nose appear sunken and tends to expose the upper teeth. The cranial bones are thickened ("bossing"), the eyelids may be puffy, and there may be an epicanthal fold; thus the designation "mongoloid facies." From a study of 138 patients it was concluded that the cephalofacial deformities are time related and closely reflect the severity of the illness.<sup>87</sup> Mild jaundice often is present, but this may not be apparent to the patient's family. Moderate lymphadenopathy may be found, but this is never striking. Cardiac dilatation is often present, and in advanced stages there is edema with effusion into serous cavities, and ecchymoses as well as free bleeding may develop.

### Skeletal System

Roentgenograms reveal striking changes in the skeletal system. There is thickening of the diploe of the skull to several times the normal depth. The outer and inner tables are thin, the former sometimes being invisible, and perpendicular striations appear between the

tables, resulting in an appearance suggesting hair standing erect on the scalp (Fig. 26-4). In the long bones, widening due to increase in the medullary portion, decreased density of the medulla, and thinning of the compact bone of the cortex are found, the most striking findings have been in the distal ends of the femurs. In the short bones, which are often rectangular in contour, trabeculation of the medulla, giving the bones a mosaic pattern, is the characteristic finding (Fig. 26-5).

Demonstrable abnormalities of the bone structure have been observed in patients as young as 4½ months old. The earliest lesions in the skull are in the frontal bones. The lesions in the tubular bones of the extremities regress with age, while the changes in the central segments of the skeleton, such as the skull, spine, and pelvic bones, persist and increase.<sup>60</sup> Retarded pneumatization of cranial air sinuses is common. Premature fusion of a segment of the epiphysis of the proximal end of one or both humeri or the distal end of one or both femurs is relatively common.<sup>75</sup>

Spontaneous fractures are unusual, but fractures may follow minor trauma.

Renal enlargement, due to renal tubular dilatation, has been described.<sup>78</sup>

Retarded growth is demonstrable after the patient is 4 years old and by the time he is 9 to 10 years old it often is significant.<sup>85,89</sup> However, except for diminished urinary excretion of 17-ketosteroids, endocrine function has not been found to be abnormal.<sup>85</sup> Some degree of sexual infantilism is common and secondary sexual characteristics develop late or not at all. Menarche is usually delayed or does not occur. As might be expected in chronically ill children, abnormal emotional responses, depressed mood, and floating anxiety have been observed, but no significant deviations from normal intelligence patterns have been found.<sup>85</sup>

In patients treated with frequent transfusions, pancreatic endocrine dysfunction and selective pituitary dysfunction with altered gonadotropin and thyrotropin reserve have been demonstrated in some instances.<sup>70,86</sup>

### The Blood

The anemia is usually pronounced when it is first discovered.<sup>66,73,104</sup> The red cell count is often between  $2 \times 10^{12}$  and  $3 \times 10^{12}/l$  but it may be as high as  $4 \times 10^{12}$  or as low as  $1 \times 10^{12}/l$ . The reduction in hemoglobin (2.5 to 6.5 g/dl) and in volume of packed red cells (0.11 to 0.24 l/l) is even greater, the anemia being hypochromic (MCHC 23 to 32 g/dl RBC), microcytic (48 to 72 fl) in type.

The appearance of the red corpuscles is very characteristic (Fig. 26-6). These cells vary greatly in size, ranging from 3 to 15  $\mu m$  in diameter. They contain little pigment and may be so distorted in shape and unusual in appearance that they appear to be composed

almost exclusively of a thin, nearly colorless membrane. The hemoglobin that is present may outline only the periphery. It may also form a circular area in the center (target cell) or there may be a bridge joining the central and peripheral zones of pigment. Few fully colored cells are present.

In wet preparations the distortion of the red corpuscles is still more evident and there may be considerable fragmentation.<sup>74</sup> The edges of some corpuscles may be folded over and then the several layers may be seen to be remarkably transparent.

The presence of nucleated red cells is a characteristic finding. There may be only 10 or 20 per 100 leukocytes, or they may be several times as numerous as the white cells; in absolute terms,  $0.20$  to  $125.0 \times 10^9/l$  may

Fig 26-6 Blood smear in a case of thalassemia major. Note the hypochromia, target cells and polychromatic cells. Photomicrograph (X1050)

be found.<sup>60</sup> The majority are either typical normoblasts or microblasts, and a number of very immature normoblasts may be seen. These cells were well illustrated and described by Kato and Downey.<sup>84</sup> They are unlike the megaloblasts found in pernicious anemia (Plate IX, page 570).

In addition, other signs of active red cell regeneration, such as polychromatophilic cells, stippled erythrocytes, and occasional corpuscles with Howell-Jolly bodies, are found in the blood. Reticulocytes are increased, often to 5 or even 15%.

Although in some instances slight initial hemolysis has been noted in 0.54% saline,<sup>66</sup> *osmotic fragility* of the red corpuscles in the main is decreased. Hemolysis may not be complete in 0.2% saline and sometimes not even in water; a pale, gelatinous layer remains in the bottom of the test tubes.<sup>66,74</sup>

As already discussed, *inclusion bodies* may be found,<sup>12</sup> similar to those seen in Hb H disease (page 879) and in the unstable hemoglobin disorders (Chapter 24). These are large, usually single, have the staining prop-

erties of Heinz bodies, and develop spontaneously. They are most frequent in normoblasts and decrease in number in more mature cells, but they are "unmasked" by splenectomy. They consist to a great extent, if not exclusively, of precipitated  $\alpha$ -chains.<sup>12</sup>

As in certain other conditions associated with rapid cellular proliferation, megaloblastic anemia associated with folic acid deficiency (Chapter 14) has been observed in thalassemia major.<sup>100</sup>

The leukocytes often are increased in number, counts of  $10.0$  to  $25.0 \times 10^9/l$  being common. There may be well-marked myeloid stimulation with many immature forms, including myelocytes and myeloblasts.<sup>81</sup> As a rule, however, these forms are not numerous. Monocytes may be somewhat increased in number or, especially in infants, there may be lymphocytosis.

No significant abnormalities in the platelet count or coagulation mechanism<sup>79</sup> have been described.

The bone marrow was described earlier (page 859). Appropriate staining reveals an abundance of iron in the reticuloendothelial cells and a number of ringed sideroblasts.

*Bilirubinemia* (1 to 3 mg/dl) of the unconjugated variety is present and the icterus index is slightly or moderately increased (8 to 30). Erythrocyte protoporphyrin is increased.<sup>90</sup> The plasma copper may be increased above normal.<sup>71</sup> The serum iron is high<sup>71</sup> and serum transferrin is often totally saturated.<sup>101</sup> Serum glutamic oxaloacetic transaminase (SGOT) and lactic hydrogenase (LDH) activities usually are elevated.

### Urine

The urine often contains slightly or moderately increased quantities of urobilinogen or urobilin, and may be dark brown, due to increased excretion of dipyrroles and mesobilifuscin (Chapter 5, page 214). An occasional iron-laden, kidney epithelial cell may be found in the urinary sediment. The output of amino acids in the urine was found to be markedly increased in children with thalassemia major.<sup>72</sup>

## Kinetic Studies

Red cell survival generally ranges from 7 to 22 days, as measured by  $^{51}\text{Cr}$ -labeling.<sup>51</sup> As mentioned earlier (page 862) there are two populations of cells, a short-lived cell population containing predominantly Hb A<sub>2</sub>, and longer-surviving cells containing relatively more Hb F. Ferrokinetic studies<sup>16</sup> indicate that iron is rapidly removed from the plasma, but incorporation into red cells is markedly reduced, the iron being shunted to the RES. The plasma iron turnover rate (PITR) may be as much as ten times greater than normal, while erythrocyte iron turnover is only slightly elevated. Combined [ $^3\text{H}$ ] thymidine incorporation and microspectrophotometry indicated marked arrest of proliferation, the major fault being in the early polychromatophilic normoblast stage of maturation.<sup>96,108</sup>

## Hemoglobin Pattern

Table 26-1 lists the amounts of Hb A, Hb A<sub>2</sub>, and Hb F that may be encountered in the various genotypes of homozygous  $\beta$ -thalassemia. There are various degrees of increase in Hb F and low, normal, or elevated levels of Hb A<sub>2</sub>. Hb A may be totally absent. A trace of slowly migrating material which usually comprises less than 0.5% of the total hemoglobin has been identified as free  $\alpha$ -chain.<sup>77</sup> It seems likely that marked differ-

ences occur in the amount of Hb F synthesized in individual red cell precursors.<sup>56</sup> Some of the variability in Hb A<sub>2</sub> levels is attributable to the fact that the measurement is recorded in terms of total hemoglobin, rather than in relation to Hb A.<sup>127</sup> When calculated as A<sub>2</sub>/A<sub>1</sub>, the A<sub>2</sub> level will be increased in patients in whom Hb F levels are very high.

## Prognosis

The classical form of Cooley's anemia was recognized as being very serious and ultimately fatal, even in the first year of life.<sup>66,73</sup> Intercurrent infection was the usual cause of death, but cardiac failure, perhaps related to the heavy deposits of iron in the myocardium, was not rare.<sup>105</sup> Improved management of infections and better general health care have favorably affected prognosis. The influence of frequent transfusions and of splenectomy will be discussed below (page 867).

As already discussed, it is now recognized that more than one variety of homozygous  $\beta$ -thalassemia exists (Table 26-1) and the severity of the clinical manifestations differs in degree with corresponding differences in prognosis.

In classical Cooley's anemia, crises and remissions are unusual. The accelerated rate of erythropoiesis may lead to increased re-

Table 26-2. Manifestations of Various Clinical Forms of Thalassemia

	Major	Intermediate	Minor	Minimal
Severity of manifestations	++++	++	+, ±	±, 0
Genetics	Homozygotes	Homozygotes, double heterozygotes, rarely heterozygotes	Heterozygotes	Heterozygotes
Splenomegaly	++++	++, +++	+, 0	0

Nucleated red cells	+++	+, 0	0	0

quirements for folic acid,<sup>82,100</sup> especially if dietary folate is marginal, or, in thalassemia intermedia, if pregnancy occurs.<sup>92</sup> Response to folic acid therapy has been observed to be associated with diffuse, intense bone pain and tenderness, especially in the lower extremities.

The long-term prognosis is poor because of the cardiac, hepatic, and endocrine damage resulting from the siderosis, this complication often having been aggravated by blood transfusion. In the absence of siderosis of marked degree, and if the infections which may develop are satisfactorily controlled, survival may extend into adolescence and even into adult life.<sup>17,56,146</sup>

### Treatment

Except in the severest forms of the disease, adaptation to the state of chronic anemia is remarkably good. Needless to say, treatment with iron is contraindicated, and copper, cobalt, organ extracts,<sup>55</sup> pyridoxine, and vitamin B<sub>12</sub> are of no value. Even folic acid is useless unless a relative deficiency develops. The claim that vitamin E protects some tissues from certain of the toxic effects of iron overload or has other beneficial effects requires further investigation.<sup>81</sup> Two forms of treatment deserve discussion, however, namely, blood transfusion and splenectomy. An objective, as yet only for the future, is the correction of the genetic defect by manipulation or modification of the protein-synthesizing machinery of the red cells in such a manner that the normal gene product is synthesized even though a mutation still exists in the patient's DNA.<sup>65</sup> Less ambitious, but also not yet possible, is the induction of fetal hemoglobin synthesis by arresting the switch from  $\gamma$ - to  $\beta$ -chain synthesis, or suppression of  $\alpha$ -chain synthesis, thereby to decrease  $\alpha$ -chain precipitation. As yet, bone marrow transplantation presents more problems than promise.

### Blood Transfusion

The occasional transfusion of blood has little value and should be avoided. As men-

tioned earlier, patients, especially children, with chronic anemia adapt remarkably well to even severe degrees of anemia. Any beneficial effects of transfusions are only of temporary value and yet, in time, will significantly increase the degree of hemosiderosis with all its consequences. Clearly, however, in children with severe grades of anemia, with hemoglobin levels as low as 5 or 6 g/dl or lower, blood transfusion is necessary to maintain life and normal activity. For such patients, a program of regular transfusions, in amounts sufficient to raise the hemoglobin level to 9 or 10 g/dl and maintain it there, is widely acclaimed as being worthwhile if begun early in life, probably no later than when the child is 6 years of age and preferably sooner.<sup>109</sup> To accomplish this, 400 to 900 ml whole blood, at intervals of 20 to 30 days, must be given and, at the cost of an extra iron burden of 2 to 4 g iron per year, improvement in general health and activity, decrease in heart, liver, and spleen size,<sup>94</sup> and, if undertaken before the age of 4 years,<sup>87</sup> prevention or amelioration of bone changes have been claimed.<sup>67</sup>

In patients with thalassemia of less severity, the benefits of blood transfusion must be weighed against the ill effects of the hemosiderosis which is ultimately induced, as well as the inconvenience and expense of blood transfusions given every three or four weeks. Transfusion siderosis may cause some degree of endocrine function,<sup>70,86</sup> as has been mentioned (page 864), and prepubertal growth is not improved and may be depressed.<sup>68</sup> Other risks must also be considered, such as the transmission of hepatitis. Furthermore, it is not known whether a long-continued program of regular transfusion therapy prolongs life. Most investigators would question the wisdom of instituting transfusion therapy in patients with hemoglobin levels of say 7 g/dl or higher.

Iron loading as the result of repeated blood transfusions can be controlled in some degree by the use of an iron chelator, desferrioxamine (DF)<sup>103</sup> being preferable to diethylenetriaminepentaacetic acid (DTPA).<sup>91</sup> The average intramuscular dose of DF will cause the urinary excretion of approximately 10 mg of

iron. Since 250 ml packed red cells contribute about 250 mg of iron, if this amount of blood is given every 20 to 30 days, daily injections of DF would have to be given to prevent progressive accumulation of iron. This is rather impractical and, with most transfusion regimens, less DF is given. Clearly, better iron chelators are needed. It has been reported that daily oral administration of 200 mg ascorbic acid increases the response to DF.<sup>93</sup>

### Splenectomy

Splenectomy has been advocated<sup>102</sup> when anemia has begun to develop more rapidly following blood transfusion than previously, the implication being that the accelerated red cell destruction is due to an extracorporeal mechanism. The spleen also has been removed when thrombocytopenia of severe degree has developed,<sup>182a</sup> presumably due to splenic sequestration, or when the size of the spleen has become so great as to cause extreme discomfort.<sup>97,105</sup> However, especially in children under 4 years of age, the risk from the development of sudden, overwhelming infection appears to be much greater following splenectomy than in older children; in thalassemia major, this risk seems to be much higher than following splenectomy for more benign conditions.<sup>76</sup> The pneumococcus has been the most frequent organism involved, and for this reason daily prophylactic administration of penicillin or sulfisoxazole has been recommended for a younger child for a year or two after splenectomy. Raised anti-streptolysin titers have also been reported and it has been suggested that benign pericarditis occurring post-splenectomy is attributable to such streptococcal infections.<sup>106</sup> Serum immunoglobulin levels for IgG and IgA have been found to be increased after splenectomy<sup>101,106</sup> but whether IgM is increased<sup>101</sup> or reduced<sup>106</sup> is unsettled.

The decision whether a given patient should be treated by transfusions, a splenectomy, or both, or if neither method should be employed is a most difficult one. Both procedures carry risks; the potential benefits must be weighed in each case, and reeval-

uated from time to time in the same case. There is a paucity of conclusive data on which the decision can be based.

### Complications

Complications, such as infections, must be met as they arise. Epistaxis is not uncommon, but is unrelated to any abnormality in coagulation or thrombocytopenia. Severe facial deformity has been corrected surgically.<sup>83</sup>

### Thalassemia Intermedia

As has been stated, thalassemia intermedia refers to cases in which the clinical manifestations are intermediate in severity between Cooley's anemia (thalassemia major) and thalassemia trait (thalassemia minor) and should be used only in a clinical sense. It has been used to apply to less serious forms of the homozygous disease,<sup>113,114,117,120,132</sup> but it has also been applied to patients who seem to be heterozygous<sup>116</sup> (Table 26-1). Some patients with clinically benign cases of thalassemia major may be doubly heterozygous for two different types of retardation of  $\beta$ -chain synthesis,<sup>120,128,137</sup> eg, heterozygosity for  $\beta$ -thalassemia and ( $\delta\beta$ )-thalassemia,  $\beta$ -thalassemia and a structural hemoglobin variant, or  $\beta$ -thalassemia and Hb Lepore.

The degree of globin precipitation in the marrow of patients with thalassemia intermedia has been found to be much milder than in patients with classical cases of Cooley's anemia<sup>61</sup>; this probably is an important factor influencing the severity of the clinical manifestations. In two reported families, inheritance of both  $\alpha$ - and  $\beta$ -thalassemia produced a clinical syndrome of intermediate severity. It was postulated that, with fewer excess  $\alpha$ -chains available than in homozygous  $\beta$ -thalassemia, intramedullary and peripheral hemolysis were less pronounced.<sup>123</sup>

Patients with thalassemia intermedia may survive into adult life,<sup>118</sup> and even enjoy a full life span.<sup>137</sup> Chronic anemia of various degrees is present, and other manifestations such as splenomegaly, bone changes, and the effects of the accumulation of iron in the tissues vary.<sup>116</sup> A high incidence of masses

of extramedullary hematopoiesis, demonstrable by roentgenography,<sup>123</sup> and of cholelithiasis<sup>115</sup> has been described.

It has not been possible to prove the heterozygous inheritance of  $\beta$ -thalassemia intermedia, some claims to the contrary notwithstanding.<sup>113,131</sup> One parent of a patient with thalassemia intermedia who seemed to be normal may instead have been a carrier of the silent  $\beta$ -thalassemia gene, while the other parent had typical thalassemia trait.<sup>111,112,110</sup> In many of the reported families the propositus has been a patient with high levels of Hb F (20 to 50%) and increased levels of Hb A<sub>2</sub>.<sup>112</sup>

### Heterozygous Beta Thalassemia

#### Clinical Manifestations

The heterozygous state for  $\beta$ -thalassemia not infrequently is discovered accidentally, either during examination for unrelated symptoms, or because hypochromia, target cells, or basophilic stippling was noted in a few red corpuscles in the blood smear<sup>146</sup>; in the investigation of a moderate anemia or a palpable spleen; or in a family study. In anemic patients, often a mistaken diagnosis of iron-deficiency anemia has been made and the patients treated for this condition. The clinical picture can range from that of a patient with thalassemia intermedia, ie, chronic anemia and splenomegaly, sometimes with attacks of acute abdominal pain, hemosiderosis,<sup>145</sup> and even with skeletal changes suggestive of the homozygous state,<sup>56</sup> to the more common more benign state (*thalassemia minor*) associated with mild or no anemia, perhaps complicated by leg ulcer<sup>136</sup> or gallstones (Rietti-Greppi-Micheli syndrome, Chapter 24); or the condition may be almost entirely without recognizable features (*thalassemia minima*, *microcytemia*<sup>140</sup>) (Table 26-2). Thinning of the cortex of the long bones and osteoporosis may be noted (Fig. 26-7)<sup>138</sup> and even radiologically demonstrable tumors of extramedullary erythropoiesis may be present.<sup>126</sup> Several genotypes are listed in Table 26-1).

Fig 26-7. Femur of a boy, aged 18 years who had thalassemia minor (A), compared with that of a healthy boy of the same age (B). Note the thinness of the cortex and the generally decreased density in A.

#### Laboratory Findings

##### Blood Findings

The red cell count may be moderately elevated above normal, but MCH is reduced, as is MCV, while MCHC may be normal or only slightly reduced. In a series of 45 cases hemoglobin was  $11.6 \pm 1.04$  g/dl, MCV  $64.70 \pm 4.35$  fl (range 52 to 75), MCH  $20.26 \pm 2.23$  pg, and MCHC  $31.22 \pm 0.96$  g/dl RBC.<sup>135</sup> Because the typical erythrocytes are flat (leptocytic), they may appear normal in diameter and hypochromic even though the indices suggest that they are

microcytic and normochromic. Other findings on microscopic examination include aniso- and poikilocytosis, basophilic stippling, and target cells. These may be very striking (Fig. 26-8) and may be far out of proportion to the degree of anemia. Resistance to hemolysis by hypotonic saline solutions is strikingly increased. On the other hand, as noted previously, no red cell changes may be demonstrable (eg, in  $\beta^{thal}$ , Table 26-1).

As in thalassemia major, the plasma copper may be increased above normal, the free erythrocyte protoporphyrin may be increased<sup>11</sup> (although this is not always the case<sup>21,141</sup>) and the iron-binding capacity of the serum may be completely saturated. (See Chapter 16, page 627).

Red cell survival time may be normal or slightly shortened.<sup>31,130,134</sup> There may be modest evidence of ineffective erythropoiesis.<sup>134</sup> If a splenectomy has been performed,  $\alpha$ -chain inclusions may be found in the red corpuscles in the blood.<sup>61</sup>

### Hemoglobin Pattern

The most consistent feature of the hemoglobin pattern of thalassemia minor is an increase in the proportion of Hb A<sub>2</sub>. As compared with a value of  $2.54 \pm 0.35\%$  in 300 normal individuals, the mean level in 34 thalassemia carriers was  $5.11 \pm 1.35\%$ .<sup>127</sup> With the exception of the carriers of some unstable hemoglobins (Chapter 24) and Hb C and Hb S heterozygotes and homozygotes,<sup>80</sup> an increased level of Hb A<sub>2</sub> has not been found in any other hemoglobin abnormality.<sup>56</sup> This useful diagnostic feature is lost when there is iron deficiency, but is corrected after iron therapy.<sup>124,143</sup> The increase in Hb A<sub>2</sub> described in some patients with pernicious anemia in relapse should cause no confusion in diagnosis.<sup>121</sup>

It is not known whether the Hb A<sub>2</sub> is homogeneously distributed throughout the red cells. If it is, the absolute amount per cell can be calculated from the MCH. When this was done, the Hb A<sub>2</sub> content of the red corpuscles was about 1.0 pg as compared with

Fig. 26-8. Stained smear showing the marked hypochromia, moderate poikilocytosis, and microcytosis, as well as a few target cells in an 18 year old boy with thalassemia minor. Photomicrograph (X800)

a normal value of 0.75 pg.<sup>56</sup> The increased synthesis of Hb A<sub>2</sub> probably is due to increased activity at both  $\delta$ -chain loci. Intra-familial segregation of Hb A<sub>2</sub> values in thalassemia minor has been noted.<sup>119</sup>

Hb F either is not detectable at all or, with rare exceptions, is present in extremely small amounts.<sup>144</sup> The distribution of the fetal hemoglobin within the red cells is heterogeneous.<sup>139</sup>

### ( $\delta\beta$ )-Thalassemia

#### (F-Thalassemia, Normal Hb A<sub>2</sub> $\beta$ -Thalassemia, $\beta$ -Thalassemia Type 2)

This form of thalassemia<sup>171</sup> is the result of defective  $\delta$ - and  $\beta$ -chain synthesis. As a consequence, in the homozygous condition<sup>151,161,163</sup> the hemoglobin is entirely fetal in type ("F-thalassemia") and Hb A and Hb A<sub>2</sub> are completely absent. The clinical manifestations have been those of thalassemia intermedia and many of the reported patients have been adults. Hemoglobin levels usually have ranged from 9 to 12 g/dl.

Heterozygotes<sup>144,154,156,157,159,163,165,168,171</sup> have Hb A, Hb A<sub>2</sub>, and Hb F. The Hb A<sub>2</sub> level usually is normal but, if expressed per red cell, the absolute mean value is about 0.53 pg (normal 0.75 pg) since MCH is reduced.<sup>165</sup> Hb F values have been 5 to 20% and averaged 10.9%. There are no specific clinical features and the red cell changes are indistinguishable from those of  $\beta$ -thalassemia minor.

( $\delta\beta$ )-Thalassemia may be associated with  $\beta$ -thalassemia ("heterozygosity for ( $\delta\beta$ )- and  $\beta$ -thalassemia"<sup>154,157,165,169,170,171</sup>). The clinical features have been found to be extremely variable, ranging from anemia, jaundice, splenomegaly, and bone changes in childhood to chance discovery later in life. Hemoglobin levels have ranged from 5.3 to 13.1 g/dl. Fetal hemoglobin is in the 60 to 95% range or higher,<sup>161</sup> Hb A<sub>2</sub> usually is 1 to 2% and Hb A may or may not be demonstrable.<sup>165</sup>

Analysis of the fetal hemoglobin in a Chinese family showed that all the individuals carrying the ( $\delta\beta$ )-thalassemia gene synthesized only the G<sub>7</sub> variety<sup>159</sup> (see page 876). This differs from findings in other patients with ( $\delta\beta$ )-thalassemia.<sup>163</sup> These observations provide evidence for the heterogeneity of this form of thalassemia.

### Miscellaneous Varieties

A number of other forms of  $\beta$ - and ( $\delta\beta$ )-thalassemia have been described. Heterozygosity for ( $\delta\beta$ )-thalassemia and the  $\delta$ -chain variant, Hb A'<sub>2</sub> (or B<sub>2</sub>) was associated with the presence of hemoglobins A, F, and B<sub>2</sub>, the last amounting to 3%.<sup>152</sup> However, since Hb A<sub>2</sub> was completely absent, it would appear that the ( $\delta\beta$ )-thalassemia mutation completely suppressed the *cis*- $\delta$  gene and that the remaining normal  $\delta$ -gene was capable of increasing  $\delta$ -chain synthesis sufficiently to bring the Hb A'<sub>2</sub> (B<sub>2</sub>) to within normal range.

$\beta$ -Thalassemia ("A<sub>2</sub> F-thalassemia") with unusually high levels of Hb F in heterozygotes, 5.1 to 14.4%, and even 17%,<sup>144</sup> in contrast to the usual low or at most 5% level characteristic of thalassemia minor (page 871) has been reported.<sup>137</sup> Hb A<sub>2</sub> values were

higher (6.6%) than usually found in  $\beta$ -thalassemia heterozygotes. In the homozygous state, this variety of thalassemia produced a mild hemolytic state (thalassemia intermedia).

Deficient synthesis of  $\gamma$ - and  $\beta$ -chains in relation to  $\alpha$ -chain synthesis ([ $\gamma\beta$ ]-thalassemia) produced hemolytic hypochromic anemia at birth which became modified as the infant matured to attain the findings of  $\beta$ -thalassemia in her father and six other relatives.<sup>158</sup>

The presence of inclusions in normoblasts consisting of precipitated  $\alpha$ -chains characterized a form of heterozygous  $\beta$ -thalassemia of greater than usual severity observed in a family of Swiss-French descent.<sup>164</sup> A form of severe  $\beta$ -thalassemia which was thought to result from overproduction of  $\alpha$ -chains also has been described.<sup>55</sup>

### $\delta$ -Thalassemia

An inherited defect in  $\delta$ -chain synthesis, occurring in an individual thought to be doubly heterozygous for this condition and ( $\delta\beta$ )-thalassemia,<sup>155</sup> as well as double heterozygosity for  $\delta$ -thalassemia and hereditary persistence of Hb F, homozygous S disease and  $\delta$ -thalassemia,<sup>167</sup> and homozygosity for  $\delta$ -thalassemia,<sup>160</sup> has been described. None of the reported patients has had any clinical symptoms or hematologic changes. The importance of the recognition of  $\delta$ -thalassemia is in the fact that it explains the absence of Hb A<sub>2</sub> in certain individuals, thereby masking the presence of  $\beta$ -thalassemia, or the finding of lower levels than would otherwise be expected.<sup>56</sup>

### Association of $\beta$ -Thalassemia with the Hemoglobinopathies

#### Hb S—Sickle Cell-Thalassemia—Microdrepanocytic Disease

The earliest instances of "sickle cell anemia in white persons" were observed in persons of Greek or Italian ancestry. It was ultimately shown that these cases represented double

heterozygosity for Hb S and  $\beta$ -thalassemia.<sup>182,185</sup> Since then the condition has been found in many racial groups.<sup>56</sup> The clinical findings range from those of a disorder indistinguishable from sickle cell anemia to a practically symptom-free state. Often fewer sickle cells and more target cells are found than are usual in sickle cell anemia. The prognosis in general corresponds to the severity of the clinical manifestations. The electrophoretic pattern usually shows a preponderance of Hb S while Hb A may be as low as 5 to 10%,<sup>181</sup> or even absent<sup>184</sup>; in the form associated with the  $\beta^{\text{thal}}$  gene there is no Hb A (Table 26-1). Hb A<sub>2</sub> usually is increased. Hb F levels range from 2 to 30%. Studies of *in vitro* hemoglobin synthesis showed that an excess of  $\alpha$ -chains is produced, with resulting ineffective erythropoiesis.<sup>56</sup> In asymptomatic black subjects, however,  $\alpha$ - and  $\beta$ -type chain synthesis in bone marrow cells was balanced.<sup>175</sup>

The genetic pattern in most cases of sickle cell-thalassemia has suggested that there is allelism or close linkage between the  $\beta$ -thalassemia and the  $\beta^S$ -loci. The combination of ( $\delta\beta$ )-thalassemia with Hb S also has been described.<sup>186</sup> In these subjects, Hb A also was completely absent, the main components being Hb F and Hb S.

In addition to the above-mentioned forms of "interacting" (page 857) sickle cell-thalassemia, a non-interacting variety was described in which there was no reversal in the hemoglobin A/S ratio and the levels of Hb A<sub>2</sub> were normal or low.<sup>178</sup> The hypothesis that such cases represent double heterozygosity of  $\alpha$ -thalassemia and Hb S<sup>27</sup> is strengthened by the description of additional syndromes involving the association of  $\alpha$ -thalassemia and  $\beta$ -chain variants (page 881).

### Hb C-Thalassemia

Like Hb S-thalassemia, Hb C-thalassemia has most often been of the interacting form, the level of Hb C exceeding that of Hb A.<sup>56</sup> The reverse<sup>191</sup> is unusual. In the Negro the disorder has been symptomless, but in the reported Italian and Turkish patients variable

anemia and splenomegaly were present. The appearance of the blood smear is very similar to that of homozygous C disease (Chapter 24).

A Negro family with Hb S, Hb C, and thalassemia in various combinations has been described.<sup>180</sup>

### Hb E-Thalassemia

Hb E-thalassemia was first described in Thailand<sup>168,177</sup> and has been observed in individuals from a number of Asiatic countries.<sup>176,189</sup> The clinical picture resembles that of Cooley's anemia. The usual electrophoretic pattern reveals Hbs E and F with no detectable Hb A. The Hb F levels show wide variations.

### Other Combinations

$\beta$ -Thalassemia has been found in association with Hb D<sup>179,187</sup> and Hb G,<sup>183</sup> as well as Hb J<sup>Georgias</sup>, Hb J<sup>Baltimore</sup>, and several  $\alpha$ -chain structural variants,<sup>56</sup> and also in association with hereditary elliptocytosis.<sup>173</sup> Homozygous Hb S disease- $\delta$ -thalassemia has been observed.<sup>185</sup>

### The Hemoglobin Lepore Syndromes

In the course of a study of thalassemia in a family named Lepore, a new hemoglobin variant was discovered.<sup>208</sup> This was later shown to be composed of normal  $\alpha$ -chains combined with chains consisting of the N-terminal residues of the  $\delta$ -chain and the C-terminal residues of the  $\beta$ -chain.<sup>200</sup> In this original Lepore hemoglobin, now called Hb Lepore Washington (=Boston), the change-over from the  $\delta$ -like sequence to the  $\beta$ -like sequence has been shown to occur between positions 87 and 116 of the new chain, which, like normal  $\delta$ - and  $\beta$ -chains, is 146 residues long. Since the original discovery, two other Lepore hemoglobins have been found, Hb Lepore Hollandia<sup>202,204</sup> and Hb Lepore Baltimore,<sup>215</sup> which are unlike Hb Lepore Washington in that the positions of fusion differ, occurring between positions 22 and 50 in the

former and between residues  $\delta^{50}$  and  $\beta^{86}$  in the latter. It has not been possible to make a closer estimate of the position of fusion of the two chains because the amino acid sequences of the  $\beta$ - and  $\delta$ -chains are so similar. Hb Pylos,<sup>207</sup> Hb Lepore the Bronx,<sup>219</sup> and Hb Lepore Augusta<sup>211</sup> have been shown to be the same as Hb Lepore Washington.

### Genetic Mechanism<sup>212</sup>

Chemical studies of the Lepore hemoglobins are consistent with the interpretation that the part of the structural gene corresponding to the N-terminal end of the  $\delta$ -chain has fused to that part of the  $\beta$ -chain which corresponds to the C-terminal end of the  $\beta$ -chain (Fig. 26-9). This is possible because the two loci are on the same chromosome and probably are closely linked. It was suggested that during meiosis the  $\beta$ -locus on one chromosome has paired aberrantly with the  $\delta$ -locus on its partner chromosome.<sup>200</sup> If crossing-over occurs, a new gene would be formed which would direct the synthesis of a peptide chain with the  $\delta$ -sequence at one end and the  $\beta$ -sequence at the other.

If this hypothesis is correct, one would expect the formation of a gene which directs the N-terminal sequence of the  $\beta$ -chain and the C-terminal segment of the  $\delta$ -chain, an "anti-Lepore" gene. Three hemoglobins have been reported which have properties that might be expected of such an anti-Lepore type of hemoglobin, Hb Miyada<sup>223</sup>, Hb P Congo<sup>205,213</sup> and Hb P-Nilotic.<sup>174</sup> No clinical

evidence of thalassemia was present in these subjects, presumably because of the presence of an active  $\delta$ - and  $\beta$ -chain gene on the same chromosome as the ( $\delta\beta$ )-fusion gene, as shown in Figure 26-9.

### Clinical Manifestations

The clinical manifestations of the Lepore syndromes are similar to those of  $\beta$ -thalassemia. Heterozygous carriers, double heterozygosity for Hb Lepore and  $\beta$ -thalassemia,<sup>203,207,208</sup> ( $\delta\beta$ )-thalassemia,<sup>223</sup> Hb S,<sup>221,222</sup> Hb C,<sup>219</sup> and Hb Peterborough,<sup>210</sup> as well as homozygous individuals<sup>207,214</sup> have been described among Italians,<sup>171,201,209,212,217</sup> Greeks,<sup>207</sup> American Negroes,<sup>215,219</sup> Yugoslavs,<sup>206</sup> Turkish Cypriots,<sup>203</sup> Papuans,<sup>214</sup> Indians and Jamaicans.<sup>66</sup> In heterozygotes, slight splenomegaly may be found,<sup>207</sup> as well as slight hypochromia and other features characteristic of thalassemia minor, including slight shortening of red cell survival.<sup>216</sup> The composition of the circulating hemoglobin has been found to include Hb A, Hb F (1.3 to 14%), Hb Lepore (6 to 15%) and Hb A<sub>2</sub> (1.2 to 2.6%).<sup>221</sup> Hemoglobin electrophoresis at an alkaline pH shows the presence of approximately 10% of a slowly migrating hemoglobin, Hb Lepore. The electrophoretic mobility is identical with that of Hb S, Hb D, and Hb P (Fig. 24-2, page 807).

The homozygous state resembles that of Cooley's anemia, with severe anemia existing from childhood. The hemoglobin has con-

Fig. 26-9 Creation of a fusion gene through crossing-over within a gene, as is thought to have occurred to produce the gene for Lepore hemoglobin, and possibly also an "anti-Lepore" gene

sisted of approximately 75% Hb F, the remainder being Hb Lepore. No Hb A or Hb A<sub>2</sub> has been found. Double heterozygosity of Hb Lepore and  $\beta$ -thalassemia is likewise associated with anemia dating from early life, and with mongoloid facies and hepatosplenomegaly.<sup>218,220</sup> The picture differed in Italians and Greeks, however, since Hb A (20 to 40%) and Hb A<sub>2</sub> (1.2 to 3.0%) were found in Italian patients<sup>169,217</sup> and neither could be demonstrated in the Greek subjects.<sup>207</sup> This difference could be due to the type of  $\beta$ -thalassemia gene associated with the Lepore hemoglobin,  $\beta^{\text{thal}}$  in the Greek subjects,  $\beta^{\text{thal}}$  in the Italians.

Studies of the relative rates of synthesis of the constituent globin chains in reticulocytes of individuals with the Lepore trait showed that Hb Lepore is not preferentially destroyed. The specific activities of the  $\alpha$ - and  $\beta$ -chains of Hb A and the  $\alpha$ - and  $\delta\beta$ -chains of Hb Lepore were similar.<sup>224</sup> It is likely that Hb Lepore is synthesized at a low rate, lower than that for the  $\delta$ -chains of Hb A<sub>2</sub> and the  $\beta$ -chains of Hb A.<sup>56</sup>

### Hereditary Persistence of Fetal Hemoglobin (HPFH)

Not to be confused with F or ( $\delta\beta$ )-thalassemia (page 871) is a benign condition characterized by the persistence of fetal hemoglobin synthesis into adult life.<sup>234</sup> In contrast to the uneven distribution of Hb F in conditions in which Hb F is produced in partial compensation for defective  $\beta$ -chain synthesis, in HPFH the fetal hemoglobin is distributed uniformly among the erythrocytes.<sup>252</sup>

### Varieties of HPFH

First observed in Negro populations,<sup>233,234</sup> HPFH was later recognized in Greeks.<sup>235</sup> The two types differ from one another in that the percentage of Hb F in the Negro heterozygote is almost twice as high as that in the Greek heterozygote, and hemoglobin A<sub>2</sub> is lower in the Negro than in the Greek form, and some clinical differences are present as

well (see below). Cases described in racial groups other than Negro or Greek have mostly resembled the Negro type,<sup>230,254,256</sup> but in others the proportions of hemoglobins F and A<sub>2</sub> were intermediate between these two forms.

The pattern of inheritance of the Greek type is like that seen in Negroes, namely, a single autosomal co-dominant factor which is closely linked or allelic to the gene determining the structure of the  $\beta$ -chain or the  $\beta$ -thalassemia gene.

The "Swiss variety" of HPFH<sup>246,249</sup> probably is a fundamentally different entity. In this condition 1 to 3% Hb F is synthesized throughout life and Hb F is not uniformly distributed among the red cells.<sup>56</sup>

### Clinical Manifestations

The heterozygous state of the Negro type is not associated with clinical or hematologic abnormalities. Hb F has ranged from 17 to 38% and was identical in chemical structure to normal fetal hemoglobin.<sup>233,252,255</sup> Hb A<sub>2</sub> is somewhat low (1.6 to 2.2%).<sup>233</sup> The homozygous state<sup>259</sup> may be associated with a very mild polycythemia.<sup>232,253</sup> In one individual, who also had elliptocytosis, the reticulocyte count was slightly raised.<sup>250</sup> In the homozygotes, Hb A and Hb A<sub>2</sub> were completely lacking and the hemoglobin was 100% Hb F. Oxygen affinity was high in the ooe patient so examined,<sup>232</sup> as it is in fetal red cells.

The Negro type has been encountered in association with Hb S.<sup>233,234,236,242,245,255,258</sup> In patients homozygous for Hb S who also inherit a gene for HPFH, there usually are neither symptoms of anemia nor complications, with the rare exception of aseptic necrosis of the femoral head.<sup>233,242</sup> The relatively mild nature of the illness may be explained by the presence of Hb F in all the red cells in HPFH. It has been shown that in sickle cell anemia the cells containing the lowest levels of Hb F are destroyed prematurely.<sup>231</sup>

Other combinations have been described, eg, with Hb C.<sup>233,244,245</sup> In such cases, symp-

toms were lacking, anemia was absent or slight, but the red cells showed moderate variations in size and shape with many target cells. Double heterozygosity with  $\beta$ -thalassemia<sup>233,244,249</sup> is similar clinically to thalassemia minor or minima.

In the heterozygous state of the Greek form no clinical or hematologic abnormalities have been described.<sup>235</sup> In double heterozygotes with  $\beta$ -thalassemia, however, slight anemia (Hb 8 to 11 g/dl), icterus, and splenomegaly were found, microcytosis and hypochromia (MCH 20 to 23 pg) were present; and Hb F ranged from 26 to 43% and Hb A<sub>2</sub> from 3.8 to 5.2%. Greek-type homozygous HPFH has not been reported.

### Chemical and Molecular Considerations

In normal newborns, fetal hemoglobin is a mixture of two molecular species,<sup>251</sup>  $\alpha_2\gamma_2^{136\text{Gy}}$  (G<sub>γ</sub>) and  $\alpha_2\gamma_2^{136\text{Ala}}$  (A<sub>γ</sub>). The ratio of these two species in the normal newborn is 3:1. In Negro families with HPFH,<sup>241</sup> one group was found in which only a single type of structural  $\gamma$ -chain gene, G<sub>γ</sub>, was present. In a second group, only A<sub>γ</sub>-chains were found.<sup>238</sup> In the majority of the families studied, however, both A<sub>γ</sub>- and G<sub>γ</sub>-chains were formed, usually in the adult G<sub>γ</sub>/A<sub>γ</sub> ratio of 3:2. The ratios of Hb<sub>A<sub>γ</sub></sub> and Hb<sub>B<sub>γ</sub></sub> are not the same in all individuals with this form of HPFH, as exemplified by observations in four Indian families.<sup>251a</sup> In Greek HPFH heterozygotes, only A<sub>γ</sub>-chains were synthesized.<sup>239,240</sup>

HPFH is considered to be a form of  $\beta$ -thalassemia, in the sense that it is characterized by deficient  $\beta$ -chain synthesis. In the Negro type,  $\beta$ - and  $\delta$ -chain synthesis are completely lacking in the  $\alpha\text{S}$  position, whereas in the Greek form the deficit is only partial. Synthesis of  $\gamma$ -chain compensates for these deficits. Several genetic explanations have been proposed, including abnormalities in operator or regulator genes<sup>248</sup> or deletion of the  $\beta$ - and  $\delta$ -chain genes with persistent  $\gamma$ -chain synthesis in one or more of the  $\alpha\text{S}$   $\gamma$ -loci.<sup>56,239,241</sup>

### Differential Diagnosis of HPFH

The acid elution technique<sup>243</sup> for fetal hemoglobin determination provides an essential test in the differential diagnosis of HPFH because it permits one to see whether or not Hb F is more or less homogeneously distributed among the red cells (Fig. 26-10). In no other condition is such a uniform pattern of distribution found.

$\beta$ -Thalassemia minor of the type associated with unusually high levels of Hb F<sup>137,144</sup> (page 871) could be confused with HPFH but is distinguished by the high Hb A<sub>2</sub> level. However, in heterozygous ( $\delta\beta$ )-thalassemia, levels of Hb A<sub>2</sub> are not increased and confusion is possible, but the level of Hb F tends to be lower than in HPFH, distribution of Hb F in the red cells is heterogeneous, and MCH is low. Clinical and family studies, the presence of some evidence of hemolytic anemia, the morphologic appearance of the red corpuscles, and lower levels of Hb F distinguish sickle cell disease and sickle cell-thalassemia, as well as Hb C-thalassemia, from heterozygosity for both HPFH and Hb S, or for HPFH and Hb C, respectively. In addition, homogeneity of Hb F distribution in the red cells distinguishes not only the above conditions from HPFH but also from other diseases, such as aplastic anemia, in which Hb F may be increased in the presence of a normal level of Hb A<sub>2</sub>.<sup>252</sup>

### The $\alpha$ -Thalassemias

That deficiency of  $\alpha$ -chain production can occur was learned indirectly, first through the discovery of Hb H ( $\beta_4$ ) disease<sup>253,323</sup> and then through the characterization of Bart's hemoglobin ( $\gamma_4$ ).<sup>205</sup> The clinical manifestations of these conditions were those of thalassemia, but the hemoglobins were shown to be tetramers of normal  $\beta$ - and  $\gamma$ -chains, respectively, formed because  $\alpha$ -chain production was deficient.

#### Heterozygous $\alpha$ -Thalassemia

Characterization of  $\alpha$ -thalassemia has proved difficult because the hematologic

Fig. 26-10. Distribution of fetal hemoglobin in red cells as demonstrated by method of Kleihauer and Betke. A, Red cells from a normal adult mixed with cells from a homozygote of HPFH. Two distinct populations are seen: the darkly stained cells contain only Hb F, the decolorized cells are the ghosts of normal erythrocytes after elution of Hb A. B, Red cells from an adult heterozygote for HPFH, there is a fairly uniform distribution of Hb F. (From Shepard et al.,<sup>139</sup> courtesy of the authors and Bulletin of the Johns Hopkins Hospital.)

changes in heterozygous  $\alpha$ -thalassemia are extremely mild. Furthermore, because a defect in  $\alpha$ -chain production affects equally the synthesis of hemoglobins A,  $A_2$ , and F, the helpful clues suggesting the presence of  $\beta$ -thalassemia that are derived from measurement of levels of these hemoglobins are lacking. Measurement of  $\alpha$ - and  $\beta$ -chain synthetic rates in reticulocytes of relatives of patients with Hb H disease and the hydrops fetalis syndrome<sup>326</sup> reveal reduced  $\alpha/\beta$  synthetic ratios. These studies support<sup>351</sup> the assumption that, when available, measurement of the level of Hb Bart's in newborn infants is a good means of detecting deficiency of  $\alpha$ -chain production,<sup>309,318,383</sup> and its degree, although this may not be invariably true.<sup>300</sup> Based on such information, as well as on measurements of hematologic parameters,<sup>318</sup>  $\alpha$ -thalassemia carriers have been divided into two groups, those with detectable hematologic changes (mild anemia, low MCV and MCH, decreased osmotic fragility, Hb  $A_2$  reduced), designated  $\alpha$ -thalassemia<sub>1</sub> carriers, and those with normal hemoglobin and red cell osmotic fragility but some reduction in

MCV and MCH, designated "silent carriers" or  $\alpha$ -thalassemia<sub>2</sub>. Thus, in one series of children one to six years of age who had had 5 to 6% Hb Bart's at birth, the hemoglobin was  $11.0 \pm 2.3$  g/dl; MCV,  $71.7 \pm 4.4$  fl; MCH,  $21.7 \pm 1.7$  pg; and MCHC,  $30.2 \pm 0.28$  g/dl. In children who had had 1 to 3% Hb Bart's at birth these values were more nearly normal (Hb,  $11.7 \pm 0.65$  g/dl; MCV,  $77.7 \pm 3.5$  fl; MCH,  $25.6 \pm 2.1$  pg; MCHC,  $32.5 \pm 2.0$  g/dl).<sup>351</sup> In another report of blood findings in  $\alpha$ -thalassemia carriers of unstated age, hemoglobin was  $12.66 \pm 1.14$  g/dl; MCV,  $72.21 \pm 3.33$  fl (range 63 to 78 fl); MCH,  $23.22 \pm 1.33$  pg; and MCHC  $31.87 \pm 0.87$  g/dl.<sup>135</sup>

Clinical disorders due to deficiency of  $\alpha$ -chain production result from the interaction of (at least) these two genes<sup>339,341</sup> (Table 26-3). The clinical manifestations of heterozygous  $\alpha$ -thalassemia are similar to those of  $\beta$ -thalassemia minor. The diagnosis is suspected when the typical morphologic characteristics are detected, especially if familial transmission can be demonstrated and iron deficiency can be excluded, but there are no

Table 26-3. Classification of the  $\alpha$ -Thalassemias

Genotype	Clinical Severity	Hb Bart's in Cord Blood	Hb H in Adults (%)	Other
$\alpha\alpha$	Normal	<0.5%	0	—

$\alpha\alpha^{thal}$	Silent	1–2%	0	—
$\alpha^{thal_1}\alpha^{thal}$	Thal minor	5–6%	0*	—
$\alpha^{thal_1}\alpha^{thal_1}$	Hydrops fetalis	80–90%	±	A± Hb Portland <sup>27*</sup>
$\alpha^{thal_1}\alpha^{thal}$	Thal intermedia (Hb H disease)	25%	4–30	—
$\alpha\alpha^{CS}$	No abnormalities	0	0	<1% Hb <sup>CS</sup>
$\alpha^{thal_1}\alpha^{CS}$	Thal intermedia (Hb H disease)	—	13–19	Hb <sup>CS</sup> 2.5%

$\alpha$  = normal structural gene for  $\alpha$ -chain synthesis

$\alpha^{thal_1}$  = severe  $\alpha$ -thalassemia gene

$\alpha^{thal}$  = mild or 'silent'  $\alpha$ -thalassemia gene

$\alpha^{CS}$  = gene for Hb Constant Spring<sup>314</sup> (Hb Thai and Hb Athens may be identical)

\*See reference 307. The suggestion has been made that hemoglobin H disease may result from this genetic constitution.

completely reliable confirmatory tests in the absence of measurements of Hb Bart's levels at birth and/or measurements of globin-chain synthesis.

Normal newborn infants do not have levels of Hb Bart's in excess of 0.5%.<sup>56</sup> In Thailand, where an incidence of 20.4% Hb Bart's was found in newborn infants,<sup>317,318</sup> infants carrying 1 to 2% Bart's were designated as having  $\alpha$ -thalassemia<sub>2</sub> trait; those with 5 to 6%,  $\alpha$ -thalassemia<sub>1</sub> trait; and those with 25% or more as having Hb H disease, the latter disorder having been found on follow-up.<sup>341</sup> Infants with  $\alpha$ -thalassemia<sub>2</sub> trait had no hematologic abnormalities except significantly reduced MCH levels, whereas those with  $\alpha$ -thalassemia<sub>1</sub> trait had marked morphologic abnormalities of the red cells and a lower hemoglobin level than do normal infants. Hb Bart's concentrations in the cord blood of 17% of Yemenite Jewish infants and in that of 11% of Iraqi Jewish infants ranged from 1 to 6%.<sup>350</sup> In vitro measurements of  $\alpha$ -globin-chain synthesis in children who had

Hb Bart's levels of 5% at birth, the  $\alpha/\beta$  synthesis ratio was  $0.64 \pm 0.05$  (normal  $1.03 \pm 0.06$ ), as compared with a ratio of  $0.76 \pm 0.08$  in children with 2% Hb Bart's at birth.<sup>351</sup> The children were family members of patients with Hb H disease.

In Negroes in Baltimore<sup>283</sup> and in Africa,<sup>278,316</sup> measurements of Hb Bart's levels suggest that a form of  $\alpha$ -thalassemia which is associated with increased levels of Hb Bart's in the neonatal period may also exist in the Negro.<sup>316,335</sup> However, no typical case of Hb H disease or Hb Bart's hydrops fetalis has been described in the Negro.<sup>325</sup> Hb H disease, but no hydrops fetalis, has been reported in the Yemenite and Iraqi families.<sup>350</sup>

### Hb Bart's

Hb Bart's is a tetramer of the gamma chains of fetal hemoglobin ( $\gamma_4$ ).<sup>288</sup> A syndrome of hydrops fetalis was shown to be associated with levels of 80 to 90% Hb Bart's,<sup>299</sup> a hemoglobin which releases so

little oxygen to tissues that it is essentially useless as an oxygen-transport protein. This condition, the most devastating of all the thalassemias, is widely recognized in Southeast Asia.<sup>310,317,330,331,348</sup> The picture is that of a pale, bloated infant, either stillborn or dying within the first hour of life. Hepatomegaly is very marked, more so than splenomegaly.<sup>302</sup> There is marked anisopoikilocytosis and hypochromia, with numerous erythroblasts in the blood, variable reticulocytosis, and a hemoglobin level which ranges from 4 to 10 g/dl.

Starch gel electrophoresis of hemolysates at alkaline pH shows the hemoglobin to consist mainly of the moderately fast-moving Hb Bart's with smaller amounts of faster-moving Hb H. In the majority of cases, Hb A is absent. In addition there is an increased amount of a fetal hemoglobin of unique constitution ( $\zeta$ -chain), Hb Portland.<sup>372,332,345</sup>

The red cells of the parents of babies with the Hb Bart's hydrops fetalis syndrome show the morphologic changes of thalassemia. In addition, there are occasional cells containing inclusion bodies, findings consistent with the  $\alpha$ -thalassemia carrier state.<sup>292,319,341</sup> Hydrops fetalis thus appears to be the clinical consequence of severe, homozygous  $\alpha$ -thalassemia. This illness is more severe than homozygous  $\beta$ -thalassemia, presumably because, in the latter condition, the absence of  $\beta$ -chains can be partially compensated for by the presence of  $\gamma$ -chains, which produce hemoglobin F.

### Hemoglobin H Disease

Hemoglobin H disease is particularly prevalent in Southeast Asia,<sup>305,341</sup> the Middle East,<sup>307</sup> Greece,<sup>271,283</sup> and Cyprus.<sup>56</sup> It is found in Chinese<sup>304,323,336</sup> and has been reported sporadically in Italians (Sardinia),<sup>266,275</sup> Arabs,<sup>267</sup> Yemenite and Iraqi Jews,<sup>350</sup> and in North Europeans.<sup>285,349</sup> The clinical findings usually resemble those of thalassemia intermedia, but the manifestations vary in severity<sup>313</sup> from little disability to those of Cooley's anemia. Anemia is only mild at birth and increases during the first

year of life. Some degree of anemia is always present. The blood smear contains—in addition to microcytosis, hypochromia, and target cells—a number of tiny, misshapen red cells. Reticulocytosis (4 to 5%), polychromatophilia, stippling, and occasional Howell-Jolly bodies are found. Incubation of 3 or 4 drops of blood with 0.5 ml of 1% brilliant cresyl blue at room temperature results in the formation of intra-erythrocytic inclusion bodies (Fig. 26-11), formed by the precipitation of Hb H as the result of the redox action of the dye. Such precipitation has also been demonstrated in mature normoblasts in the bone marrow.<sup>279</sup>

Hb H, a tetramer of four normal  $\beta$ -chains ( $\beta_4$ ),<sup>200</sup> was the first reported of a series of "fast" hemoglobins<sup>323</sup> which share the electrophoretic characteristic of a faster anodal mobility at pH 8.6 than that of Hb A. It has a mobility similar to that of Hb I, from which it is distinguished by its anodal migration at pH 6.5. The total amount of Hb H in the red corpuscles of patients with Hb H disease has ranged from 4 to 30%.<sup>341</sup> A small quantity of Hb Bart's may be found<sup>286,321</sup> and Hb A<sub>2</sub> is always diminished (average 1.55%).<sup>341</sup> It was noted that, at birth, about 25% Hb Bart's was present, but this gradually decreased and was replaced by Hb H.<sup>341</sup> Although occasionally Hb Bart's levels may exceed those of Hb H.<sup>321</sup> In patients with Hb H disease in Thailand, on starch gel electrophoresis a cathodal band was described which migrated more slowly than Hb A<sub>2</sub>. This was designated Hb Thai<sup>337,342</sup> and may be the same as Hb Athens, or Hb Constant Spring (page 881), described in Greek<sup>328</sup> and Chinese<sup>277,308</sup> patients, respectively. Thus, from the standpoint of the clinical picture produced, the genes for these hemoglobins behave similarly to the "silent"  $\beta$ -thalassemia ( $\alpha$ thal) gene.

Hb H is relatively unstable and thermolabile.<sup>327</sup> Its oxygen affinity is ten times that of Hb A. There is no Bohr effect and its oxygen dissociation curve gives no evidence of heme-heme interaction.<sup>269</sup> These properties are disadvantageous to the anemic patient since less oxygen is given up at physiologic

Fig. 26-11. Erythrocyte inclusion bodies in blood of patient with Hb H-thalassemia. The inclusion bodies appeared after incubation with brilliant cresyl blue for 20 minutes at 37°C and may be seen in nearly every erythrocyte in contradistinction to the reticulum of reticulocytes (dark black bodies in the photograph) which is present in only a few cells (X1000) (From Ottman et al.,<sup>275</sup> courtesy of the authors and Henry M. Stratton, Inc.)

tensions. The ease with which Hb H is oxidized, eg, by redox dyes, may be due to the presence of eight free thiols in its four  $\beta$ -chains.<sup>280,282</sup> One of the reasons for its tendency to precipitate may be the rapid rate at which it forms hemichromes.<sup>320</sup> In vitro studies of hemoglobin production have shown that  $\beta$ -chain synthesis exceeds that of  $\alpha$ -chains by a factor of 1.5/1 to 4/1.<sup>274,344</sup> Hb H red cells have increased membrane permeability,<sup>312</sup> the rate of loss of phospholipids on incubation is increased,<sup>327</sup> and their life span is greatly shortened.<sup>281,322</sup> The extreme degree of poikilocytosis seen in Hb H disease, as judged by electron microscopic studies,<sup>347</sup> is probably the result of removal of the inclusion bodies from the red cells as they pass through the reticuloendothelial system, as well as the splitting of the corpuscles into two or more fragments during their passage from splenic cords to sinuses.

As indicated previously, it is thought that Hb H disease results from the interaction of

at least two  $\alpha$ -thalassemia genes (one of these, presumably  $\alpha^{\text{thal}_2}$ , being so mild in heterozygotes as to be completely "silent" clinically<sup>293,296,303,311,313,339</sup>) or from double heterozygosity of Hb Constant Spring and an  $\alpha$ -thalassemia<sub>1</sub> gene<sup>342</sup> (Table 26-3). An alternative suggestion is that the disorder represents the homozygous state resulting from inheritance of the mild  $\alpha$ -thalassemia gene ( $\alpha^{\text{thal}_2}$ ) from each parent.<sup>307</sup> Studies in Thailand are in keeping with both these hypotheses.<sup>311,339</sup> With one exception<sup>294,295</sup> in which both parents were affected, only one parent of patients with Hb H disease has shown hematologic abnormalities in the blood smear and normal levels of Hb A<sub>2</sub>.

#### Hb H or Hb Bart's in Acquired Disorders

Hb H has been found in the red cells of some patients with "myeloproliferative" disorders,<sup>284</sup> especially erythroleukemia,<sup>324</sup> per-

haps as the result of imbalanced chain production consequent to a chromosomal aberration. Hb Bart's has been described in the  $D_1$  trisomy syndrome.<sup>287</sup>

#### $\alpha$ -Thalassemia in Association with $\alpha$ -Chain and $\beta$ -Chain Variants

The  $\alpha$ -chain variants reported in association with  $\alpha$ -thalassemia include Hb Constant Spring, mentioned above, Hb Q, and Hb I. Hb<sup>CS</sup> (*Constant Spring*)<sup>307a,308</sup> is an extremely long chain as it is made up of 31 additional residues attached to the C-terminal end of the 141 amino acids that normally make up the  $\alpha$ -chain. It is found in approximately 50% of persons with Hb H disease in Thailand and Malaysia and in 12% in Hong Kong, and behaves like an  $\alpha$ -thalassemia<sub>2</sub> gene.<sup>273</sup> Inherited together with an  $\alpha$ -thalassemia<sub>1</sub> gene, it produces the clinical picture of Hb H disease. A similar clinical picture was found in Hb Q  $\alpha$ -thalassemia and this, like Hb<sup>CS</sup>  $\alpha$ -thalassemia, was first reported in Chinese.<sup>301,336</sup> It has since been described in Thailand,<sup>276,306</sup> Iran,<sup>306</sup> and India.<sup>329</sup> In the Oriental Hb Q, the mutation (asp  $\rightarrow$  his) is at  $\alpha 74$  (EF3); in the Iranian, at  $\alpha 75$  (EF4)<sup>306</sup>; and in the Indian, at  $\alpha 64$ . These patients were found to synthesize no normal  $\alpha$ -chains and the abnormal  $\alpha^Q$ -chains combined with  $\beta$ - and  $\delta$ -chains to produce abnormal major ( $\alpha_2^Q\beta_2$ )- and minor ( $\alpha_2^Q\delta_2$ )-hemoglobin components. Hb I  $\alpha$ -thalassemia has been reported only in one family, all members of which were Negroes.<sup>268</sup>

The  $\beta$ -chain variants that have been found in association with  $\alpha$ -thalassemia are Hb S,<sup>335,352</sup> Hb C,<sup>191</sup> Hb E,<sup>333,334</sup> and Hb J<sup>Bangkok</sup>.<sup>341</sup> The combination of Hb S or of Hb C with  $\alpha$ -thalassemia appears to be associated with minimal anemia, but there are more marked morphologic changes of the red cells and lower levels of Hb S or Hb C, respectively, than would be expected in Hb S or Hb C heterozygotes.<sup>56</sup> The association of Hb E with  $\alpha$ -thalassemia, as might be expected from the frequency of these disorders in Southeast Asia, has resulted in many different combinations,<sup>340,341</sup> of which  $\alpha$ -thalassemia<sub>1</sub>/ $\alpha$ -thalassemia<sub>2</sub>/Hb E trait is the most

common.<sup>340</sup> Except for the presence of fewer inclusion bodies, the clinical picture is like that of Hb H disease.

$\alpha$ -Thalassemia also has been found in association with  $\beta$ -thalassemia,<sup>154,270,291</sup> ( $\delta\beta$ )-thalassemia,<sup>56</sup> and HPFH. Study of the clinical and hematologic manifestations of patients with different combinations of  $\alpha$ - and  $\beta$ -thalassemia permits the assumption that, in the absence of gross chain imbalance, marked hypochromic anemia is produced but the hemolytic element is much reduced, perhaps because membrane damage<sup>312</sup> is less.

#### Genetics of the $\alpha$ -Thalassemias

The genetics of the  $\alpha$ -thalassemias has been very ably discussed by Weatherall and Clegg<sup>56</sup> who point out that, in spite of the opportunities afforded by the study of the various combinations of genetic abnormalities, a number of questions remain to be answered before the genetic transmission of  $\alpha$ -thalassemia can be considered as being understood. It is not known whether there are one or two (or even more) structural loci on each chromosome controlling the production of the  $\alpha$ -chains of normal adult hemoglobin, or even whether the situation in this respect is the same in all populations. As stated previously, in the majority of patients with Hb H disease the condition appears to have resulted from the interaction of a recognizable and a "silent" gene.<sup>296,339</sup> The possible reduplication of  $\alpha$ -chain structural genes<sup>338</sup> was discussed in Chapter 24. It has been suggested that if there are two  $\alpha$ -chain loci on each chromosome, loss of two genes would produce the detectable carrier state; three genes, Hb H disease; and four, the Hb Bart's hydrops fetalis syndrome.<sup>294,297,338</sup> If unequal crossover occurs, one can conceive chromosomes that contain one or three genes, as distinguished from the normal two. Thus,  $\alpha$ -thalassemia might be visualized as resulting from the presence of only two or three  $\alpha$ -genes.<sup>298</sup> Since chromosomes are paired, five or six genes could result from chromosomes formed from such a crossover and this would produce an excess of  $\alpha$ -chains<sup>35</sup> (page 880).

### Treatment

What was said earlier in regard to the treatment of the  $\beta$ -thalassemia syndromes applies equally well to the treatment of  $\alpha$ -thalassemia. There have been reports of benefit from splenectomy in Hb H disease,<sup>283,341,349</sup> but results have not been uniformly good. Since Hb H is unstable and precipitates in the presence of oxidant drugs, the therapeutic use of such agents (Table 23-2 and Appendix C) should be avoided.<sup>322</sup>

*Genetic counseling* is especially important in Southeast Asia where  $\alpha$ -thalassemia represents a major public health problem. When a woman has lost a child with the Hb Bart's hydrops fetalis syndrome she probably has a one in four chance of producing similar infants through the same husband. A parent of a child with Hb H disease has a similar chance of passing the disease on to another offspring.

### Geographic and Racial Distribution of Thalassemia

As judged by such simple parameters as hematologic values, osmotic fragility studies, and Hb A<sub>2</sub> levels,  $\beta$ -thalassemia is found in a broad belt extending from the Mediterranean basin through the Middle East to the Far East<sup>365</sup> (see Fig. 24-7). It is very common in Italy and Greece. In Italy it is especially common in the delta of the Po River where, in some communities near Ferrara, its incidence was found to be as high as 20%.<sup>366</sup> It is also common in the far south and in adjoining Sicily (10% or more of Sicilians are carriers)<sup>36,358,379,380</sup> and in Sardinia (11 to 34% carriers).<sup>391</sup> In Greece<sup>326</sup> the distribution of the trait is irregular,<sup>367</sup> but frequency is high in the southern and central areas.<sup>353</sup> High incidence rates have been reported in Cyprus<sup>373</sup> and in Malta.<sup>381</sup> Thalassemia has been reported sporadically in northern and western parts of Africa.<sup>56,371</sup>

In the Middle East, many cases of  $\beta$ -thalassemia have been reported from Turkey,<sup>111</sup> Iran,<sup>368</sup> and Syria<sup>357,363</sup> and in Indian and Kurdish Jews.<sup>362,375</sup> It has been described in

Arabs, especially those in Saudi Arabia.<sup>56</sup> It is noted in Pakistan and in India,<sup>356,364</sup> especially in Bombay, Calcutta, and Madras. In the Far East, thalassemia is very common, both  $\beta$ - and  $\alpha$ -thalassemia having been reported.<sup>154,168,370</sup> As has already been discussed in some detail (page 879),  $\alpha$ -thalassemia is especially common in Southeast Asia. In the population of northern Thailand,<sup>370</sup> an incidence of 4.8 to 10% has been reported.<sup>156</sup> The total number of individuals affected with different combinations of thalassemia genes in Thailand has been estimated at 223,000.<sup>168</sup> The disease is also encountered frequently in both Chinese and Malays in the Malay Peninsula and in Indonesia, New Guinea, and western Melanesia, and has been described in India.<sup>359</sup> A number of cases of Hb H disease have been reported from the Middle East (page 879).

In the United States, thalassemia is noted particularly in persons of Italian<sup>371</sup> and Greek descent. In Negroes, although  $\beta$ - and  $\alpha$ -thalassemia<sup>383</sup> have been described, the incidence is low; the manifestations usually have been mild,<sup>356,358</sup> for reasons that are obscure.<sup>354,361</sup> Only once has the  $\beta$ <sup>thal</sup> gene been reported in the Negro.<sup>39</sup> Its presence in Jamaica may originate in the Oriental immigrants.<sup>258</sup> Thalassemia is rare in American Indians.<sup>378</sup>

Though rare, thalassemia has been recognized in North Europeans without Mediterranean or Oriental ancestry.<sup>56,358</sup>

The geographic distribution of thalassemia has aroused interesting speculation.<sup>378</sup> It has been attributed to migrations and commerce carrying the defect eastward from a large pool in the Mediterranean basin, or westward from Indochina; or it may have originated in Armenia and spread both to the east and west.<sup>353</sup> Why a potentially lethal gene like thalassemia has continued to be prevalent in certain areas is uncertain. It is less well established that thalassemia confers resistance to malaria than is the case for the sickle cell trait and G6PD deficiency (Chapter 23), but it is true that the high incidence areas for thalassemia are those in which malaria has been endemic.<sup>56,382</sup>

## Diagnosis and Differential Diagnosis of Thalassemia

Thalassemia is recognized by clinical examination, hematologic studies, hemoglobin electrophoresis, measurement of Hb A<sub>2</sub> and Hb F levels (Table 26-4), and family studies. The finding of microcytosis, hypochromia, basophilic stippling, and decreased osmotic fragility of the red corpuscles will alert the physician, whereas such findings as leukopenia and thrombocytopenia, low serum iron, and high iron-binding capacity direct attention to other disorders, such as Fanconi's anemia or iron-deficiency anemia. However, as mentioned earlier (page 871), if  $\beta$ -thalassemia is associated with iron deficiency, the Hb A<sub>2</sub> level falls, thereby leading to confusion. Hemoglobin electrophoresis will reveal the presence of Hb S, Hb C, Hb D, or Hb E, but does not exclude double heterozygosity for a hemoglobinopathy together with  $\beta$ -thalassemia. Marked hypochromia, microcytosis, and some stippling are found in sideroblastic anemias, but in those conditions

a double population of red corpuscles is likely to be noted (Chapter 18). A rapid screening test based on electronic size distribution curves has been reported to be very helpful in distinguishing thalassemia trait from both normal and sideropenic disorders.<sup>142</sup>

If splenectomy has already been carried out, inclusion bodies in the red cells will be found if one is dealing with unstable hemoglobin (Chapter 24) and if the associated hemoglobin variant has a neutral amino acid substitution, the heat precipitability test will be needed to distinguish an unstable hemoglobin from thalassemia.

Hb F levels may be markedly increased in acquired conditions, such as the di Guglielmo syndrome (Chapter 18) and juvenile chronic myelocytic leukemia.<sup>56</sup> In sideroblastic anemias, Hb F may be somewhat increased and Hb A<sub>2</sub> usually is low. Hb F also may be slightly increased in pernicious anemia, myelofibrosis, aplastic anemia, and even in paroxysmal nocturnal hemoglobinuria.<sup>56</sup> Hb A<sub>2</sub> levels may be increased in megaloblastic anemias.<sup>56</sup> Careful clinical examina-

Table 26-4. Hemoglobin Constitution in Some of the Thalassemias

	RBC Morphology	Hb	Hb A <sub>2</sub>	Hb F	Abnormal Hb
<b>Homozygotes</b>					
$\alpha$ -thalassemia	Thalassemic	—	—	Variable	Hb Bart's
$\beta$ -thalassemia	Thalassemic	—, 0	+ N, —	++	$\alpha$ -chains
( $\delta\beta$ ) thalassemia	Thalassemic	0	0	++++	0
$\delta$ -thalassemia	Normal	N	0	N	0
Hb Lepore	Thalassemic	0	0	++	Hb Lepore
HPFH	Normal	0	0	100%	0
<b>Heterozygotes</b>					
$\alpha$ -thalassemia	Thalassemic	+	N	N	Hb Bart's $\pm$ Hb H $\pm$
$\beta$ -thalassemia	Thalassemic	N —	++	N (+)	0
( $\delta\beta$ )-thalassemia	Thalassemic	N, —	N	++	0
$\delta$ thalassemia	Normal	N	—	N	0
Hb Lepore	Thalassemic	N, —	—	+	Hb Lepore
HPFH	Normal	—	—	++ (Homogeneous distribution)	0
<b>Double heterozygotes</b>					
Hb S $\beta$ thalassemia	Thalassemic; sickling	—	+	+	Hb S
Hb E $\beta$ -thalassemia	Thalassemic	0	0?	+	Hb E
Hb E $\alpha$ thalassemia	Thalassemic; Hb H	+	?	+	Hb E
					Hb Bart's in some

tion will almost always make differentiation possible.

To differentiate the various forms of thalassemia, family studies and relatively sophisticated laboratory tests are needed. The absence of any anemia and the normal appearance of the red cells in hereditary persistence of fetal hemoglobin (HPFH) distinguish this condition from homozygous ( $\delta\beta$ )-thalassemia. Its differentiation from  $\beta$ -thalassemia minor was discussed earlier (page 876). The combination of  $\alpha$ -thalassemia with HPFH may produce a picture similar to that of heterozygous ( $\delta\beta$ )-thalassemia, but Hb H inclusions or the presence of small amounts of Hb Bart's on starch gel electrophoresis point to the coexistence of  $\alpha$ -thalassemia.

Detection of the  $\beta$ -thalassemia trait at birth was accomplished by measuring the incorporation of  $^{14}\text{C}$ -leucine into the  $\alpha$ -,  $\beta$ -, and  $\gamma$ -chains. In an affected infant, the presence of one  $\beta$ -thalassemia gene was revealed on the first day of life by the lower specific activity of the  $\beta$ -chain.<sup>122</sup> In the red cell precursors of newborn infants with  $\beta$ -thalassemia, inclusion bodies have been observed.<sup>61</sup>

As discussed earlier (page 876) the  $\alpha$ -thalassemia traits are very difficult to recognize, since a defect in  $\alpha$ -chain synthesis affects equally the synthesis of hemoglobins A, A<sub>2</sub>, and F. The measurement of Hb Bart's in the neonatal period is very helpful, but in adult life the most that can be expected is slight hypochromia and minor changes in the red cell indices. Hb H disease (page 879) is usually recognized by the association of a thalassemia-like picture with intracellular inclusions precipitated by brilliant cresyl blue (Fig. 26-11). A history of repeated hydropic stillbirths in an Oriental woman strongly suggests that Hb Bart's is the cause. The hemoglobin pattern of the stillborn or examination of blood obtained by amniocentesis of a suspected pregnant woman will reveal the abnormal hemoglobin if this, rather than neonatal hemolytic disease due to Rhesus or ABO incompatibility, is the cause.

Incompatible Transfusion Reactions  
Hemolytic Disease of the Newborn  
Hemolytic Disease of the Newborn Due to  
ABO Incompatibility  
Immunochemolytic Anemias Due to Warm  
Reactive Antibodies  
Drug-Induced Immunochemolytic Anemias  
Immunochemolytic Anemias Due to Cold  
Reactive Antibodies

### **Incompatible Transfusion Reactions**

The clinical aspects of transfusion reactions were discussed in Chapter 11. The mechanisms of hemolysis due to ABO and Rh antibodies will be considered here because they serve as prototypes of the reactions occurring in other acquired immunochemolytic anemias.

#### **Red Cell Destruction by ABO Antibodies**

Hemolytic reactions due to ABO incompatibility are brought about by isoantibodies with exquisite specificity for ABO blood group substances. These antibodies develop early in life in response to repeated exposure to ABO-like substances found in food, bacteria and other exogenous materials and are always found in the serum when the corresponding antigen is lacking on the red cells

(Table 11-1). Thus prior transfusion is not necessary for sensitization to occur. Although ABO antibodies may belong to any of the major immunoglobulin classes, group A and group B subjects are known to have predominantly IgM anti-B and anti-A antibodies, respectively, whereas group O subjects commonly develop IgG antibodies as well.<sup>107</sup> When antibodies are present in low concentrations they appear to have only agglutinating properties *in vitro*, hemolytic activity being undetectable with present techniques. When present in higher concentrations, both the IgM and IgG antibodies can be shown to have complement-dependent lytic activity *in vitro*<sup>107</sup>; in the absence of complement, only the agglutinating properties are demonstrable. Because these antibodies are capable of agglutinating red cells suspended in saline solution, they are termed "complete antibodies."

Jandl<sup>9</sup> and others<sup>8,13,15</sup> conducted illuminating studies on the fate of <sup>51</sup>Cr-labeled red cells infused into ABO incompatible recipients. When small volumes of such cells are infused into individuals with normal levels of isoagglutinins but no demonstrable isohemolysin activity, the red cells are quickly removed from the circulation, half the labeled erythrocytes being cleared in just under two minutes. Moderate hemoglobinemias develop rapidly and surface counting shows marked and rapid accumulation of radioactivity over the liver.

In subjects with demonstrable agglutinin and low levels of hemolysin activity the pattern is similar except that high levels of  $^{51}\text{Cr}$  and hemoglobin appear in the plasma immediately after the injection of cells and decline during the next several hours. In subjects with high levels of hemolysins, hemoglobinaemia appears abruptly and is pronounced, reflecting the virtually instantaneous destruction of incompatible cells by complement-dependent mechanisms. At least 80% of the hemoglobin contained in the injected cells can be found in the plasma, peak levels being reached in less than 60 seconds. Under these circumstances, accumulation of radioactivity over the liver is considerably slower and less marked than in the presence of isoagglutinins only. As described in Chapter 5, the free hemoglobin or heme is removed by renal excretion or by complexing to haptoglobin, hemopexin, or albumin, with subsequent clearance by the reticuloendothelial system (RES); the red cell membrane most likely is also removed by the RES, predominantly in the liver and the spleen.

The observations just described were made when relatively small volumes of cells were being destroyed under conditions of excess antibody, complement, and other serum factors. Under appropriate circumstances the destruction of larger numbers of cells has been shown to proceed more slowly because the number of erythrocytes introduced into the circulation may significantly decrease the concentration of available antibody.<sup>107</sup> This applies especially to ABO-incompatible transfusions since the number of A and B antigen sites per red cell is considerable, being at least 100 times greater than, for instance, the number of D-antigen sites.<sup>213,254-251</sup> When the serum contains potent antibodies, however, even large ABO-incompatible transfusions may not remove all anti-red cell activity from the circulation.

#### Red Cell Destruction by Rh Antibodies

Antibodies to Rh antigens differ significantly from anti-A or anti-B antibodies.

1. Anti-Rh antibodies do not occur "naturally" but are synthesized in response to stimulation by foreign red cells bearing the appropriate antigenic determinants.

2. Anti-Rh antibodies are predominantly IgG globulins,<sup>107</sup> although, early in the immune response, gamma M antibodies may also be prominent. Only occasionally are IgA Rh antibodies encountered.<sup>107</sup>

3. Antibodies to Rh antigen usually do not fix complement and are rarely lytic in vitro<sup>25,26</sup> even though Rh antibodies were shown to belong predominantly to the IgG1 and IgG3 subclasses and are therefore structurally equipped for complement fixation<sup>269,271</sup> (Chapter 7). It is possible that the lack of complement fixation by the red cell-bound anti-Rh antibodies is related to the relative sparsity of specific Rh antigenic sites on the cell surface,<sup>281</sup> since two adjacent IgG molecules are required for activation of complement to occur.<sup>4</sup> In keeping with this interpretation, complement activation can be demonstrated if red cells are treated with a combination of specific antisera, for instance anti-hr' (c), anti-Rh<sub>0</sub> (D), anti-rh" (E)<sup>22</sup>

4. With the exception of the early IgM antibodies, anti-Rh antibodies do not lead to agglutination of red cells in saline solution and are therefore considered to be "incomplete" antibodies. This phenomenon is not fully understood but may be related to the molecular length of the IgG antibody,<sup>20</sup> the relative sparsity of antigenic sites per red cell,<sup>281</sup> or other repulsive forces that prevent the erythrocytes from approaching close enough to allow the antibody to bridge the gap.<sup>19</sup> Such repulsive forces include the like negative charge on the surface of all erythrocytes, and the cloud of cations attracted by the surface negative charge; the net potential of these two layers is normally negative, is directed toward the outer aspect of the cloud, and determines the net repelling force between two cells. It is referred to as the zeta potential and equals 15 millivolts in isotonic solutions; the maximal zeta potential at which human red cells can be agglutinated by "complete" (IgM) agglutinins is 18 to 20 millivolts, while for incomplete (IgG) an-

tibodies it is only 8 to 9 millivolts.<sup>20</sup> Albumin and other colloids such as fibrinogen or polyvinyl pyrrolidone reduce the zeta potential by their higher dielectric constants that drain away the net negative charge and thereby enhance the agglutinating potential of incomplete antibodies.

### Coombs' Antiglobulin Tests

The presence of anti-Rh antibodies on the surface of red cells is most readily demonstrated by means of the *direct Coombs' test* (direct antiglobulin test) (Fig. 27-1). The reagents for this test are prepared by immunizing rabbits with whole human serum, gamma globulin, or complement. The result-

ant antisera may be appropriately absorbed to yield reagents with specificity for a given gamma globulin class or complement. When cells sensitized with incomplete antibodies or complement components are suspended in the appropriate (Coombs') antiserum, agglutination of the cells results. Nonsensitized cells so treated do not agglutinate, although rare exceptions have been noted.<sup>23</sup>

The technique of the direct test has been modified to detect anti-red cell antibodies present in the serum; this test is known as the *indirect Coombs' test* (indirect antiglobulin test). In this procedure, various types of normal red cells are incubated in the patient's serum under appropriate conditions. After being washed free of nonspecifically adherent

Fig 27-1. Direct Coombs' test Rabbits or goats are immunized with human serum or serum components. The resulting sera containing anti-gamma globulin or anti-complement antibodies are then added to test samples of red cells. If human gamma globulins and/or complement components are bound to the cell surface, agglutination occurs.

gamma globulin or complement they are tested by Coombs' serum as in the direct procedure. Agglutination indicates the sensitization of normal cells by gamma globulin, or complement components, depending on the type of Coombs' antiserum used. As discussed elsewhere (page 472) the indirect antiglobulin test can be made more sensitive by treating normal test cells with proteolytic enzymes. This manipulation may even lead to agglutination of cells by incomplete antibodies in the absence of antiglobulin sera.

### Site of Destruction

When small volumes of  $^{51}\text{Cr}$ -tagged  $\text{Rh}_0(\text{D})$  red cells are injected into individuals with relatively high titers of incomplete anti- $\text{Rh}_0$  antibodies, the labeled erythrocytes are quickly removed from the circulation and there is a concomitant increase of radioactivity over the spleen and to a much smaller degree over the liver.<sup>3,6,9</sup> The half-life of these cells in the circulation is only a few minutes and very little hemoglobin or nonerythrocyte  $^{51}\text{Cr}$  appears in the plasma, attesting to the predominantly extravascular destruction of red cells coated by incomplete antibodies. Even when larger volumes of Rh-incompatible red cells are given, the circulating hemoglobin does not reach levels higher than those that would be derived from 12% of the total number of cells infused; in addition, the peak of extracellular hemoglobin is reached an hour after transfusion, suggesting that intravascular spillage occurs only when the mechanisms for removal of extravascularly released heme proteins have been saturated.<sup>9</sup> The mechanism of hemoglobin release under these circumstances is obscure.

Extravascular splenic destruction of anti-Rh antibody-coated red cells occurs over a wide range of antibody concentrations.<sup>16</sup> The speed of removal from the circulation appears to depend on the amount of antibody coating the red cells: antibody concentrations of the order of 25/ $\mu\text{g}/\text{ml}$  of red cells (corresponding to a titer of  $1/64$  or more) are required to bring about their clearance with a single passage through the spleen, the clear-

ance half-time being about 20 minutes. Antibody concentrations of less than 5  $\mu\text{g}/\text{ml}$  of red cells and corresponding to titers of  $1/8$  or less may bring about the removal of red cells in a half-time of 60 to 100 minutes.<sup>6,16</sup> The liver clears red cells coated with "incomplete antibodies" much less efficiently than does the spleen.<sup>16</sup> Even when erythrocytes are sensitized with as much as 40  $\mu\text{g}$  of antibody per milliliter of red cells, only about one third are cleared by a single passage through the liver. Nevertheless, the liver plays a *clinically* significant role in the destruction of red cells, especially of those coated by high concentrations of antibody.<sup>213a</sup>

The way in which the RES destroys anti-Rh antibody-tagged erythrocytes is not fully understood. LoBuglio et al.<sup>11</sup> and others<sup>2</sup> demonstrated, *in vitro*, the binding of antibody-coated red cells to monocytes and macrophages, accompanied by rapid phagocytosis and red cell fragmentation. The receptor site on the macrophage has specificity for the Fc portion of the IgG molecule and seems to be distinctly different from the site that binds IgM-complement-coated red cells. A further mechanism of splenic red cell destruction is suggested by the observation that agglutinates consisting of red cells coated by incomplete antibodies are numerous in splenic blood and may indeed escape into the peripheral circulation.<sup>245</sup> It is likely that the high VPRC of splenic blood and the higher protein concentration of the intrasplenic plasma<sup>24</sup> create conditions that induce agglutination of sensitized cells (see above) and their subsequent sequestration. Because of the metabolically unfavorable environment of the spleen<sup>27</sup> and the partial phagocytosis by macrophages,<sup>5</sup> spherocytes may result; because of their structural rigidity the spherocytes are then destroyed by mechanisms described elsewhere (see Chapter 21). Once the cells have been sequestered, destruction appears to be complete within minutes.

The most important features of red cell destruction by "complete" (IgM) and "incomplete" (IgG) antibodies are summarized in Table 27-1.

The clinical manifestations, diagnosis, and

**Table 27-1. Red Cell Destruction by "Complete" (IgM) and "Incomplete" (IgG) Antibodies**

Antibody	Predominant Site of RBC Destruction			Complement Dependency	Hemoglobinemia	Bilirubinemia	Specificity of Coombs' Test
	Intravascular	Extravascular					
		Liver	Spleen				
Low titer anti-A or anti-B (IgM)	±	+	—	±	±	+	Anti-C'
High titer anti-A or anti-B (IgM)	+	—	—	+	+	+	Anti-C'
Low titer anti-D (IgG)	—	—	+	—	—	+	Anti-IgG
High titer anti-D (IgG)	—	±	+	—	±	+	Anti-IgG

treatment of transfusion reactions are discussed in Chapter 11.

## Hemolytic Disease of the Newborn (HDN)

In an earlier chapter (page 458) the discovery of the Rh blood group system<sup>95</sup> and the suggested role of anti-Rh antibody in the pathogenesis of HDN<sup>97</sup> were described. Since that discovery it has been learned that HDN may be produced in a number of other ways as well (Table 27-2). This discussion, however, will deal almost exclusively with hemolysis caused by maternal antibodies against fetal cells.

### Etiology and Pathogenesis

When fetal red cells cross the placenta, they may stimulate the production of maternal antibodies against those fetal antigens that are not inherited from the mother and are therefore regarded as foreign. Some of these antibodies then cross into the fetal circulation and cause the destruction of fetal red cells. Fetal-maternal ABO incompatibility is responsible for two thirds of all cases of HDN,

but Rh incompatibility, which accounts for most of the remainder, is clinically the more important because it causes disease of far greater severity.<sup>36</sup> A few cases, perhaps 2% of the total, involve minor antigens such as hr'(c), rh''(E), rh''<sup>W2</sup>(E<sup>W</sup>), and Kell.<sup>122</sup> Most of the following discussion will deal with hemolytic disease due to Rh incompatibility. That due to ABO incompatibility will be discussed separately (page 908).

### Passage of Fetal Cells into the Maternal Circulation

Direct proof that fetal erythrocytes enter the maternal circulation was obtained in 1954 when Chown demonstrated the transfer of large amounts of blood (160 ml) by use of the differential agglutination technique.<sup>54</sup> Subsequently a more sensitive method for the detection of fetal erythrocytes was developed by Kleihauer, Braum, and Betke<sup>91</sup>; this method depends on the demonstration of cells containing hemoglobin F by the acid elution technique. The test is a sensitive one, making possible the detection of as little as 0.05 to 0.1 ml of fetal blood in the maternal circulation. By its use, small numbers of fetal cells have been demonstrated in the maternal

---

circulation as early as the third month of pregnancy.<sup>59, 167</sup> However, the chances of finding fetal cells in mothers' blood appear to increase as pregnancy progresses; an incidence of 28.9% in the third trimester was reported.<sup>59</sup> Others noted an overall incidence of 15.8% throughout pregnancy<sup>167</sup> and observed that the frequency with which fetal cells were found increased with the number of examinations made, reaching 43.6% in those examined five times.<sup>167</sup> Thus the transplacental passage of small amounts of fetal blood (less than 0.1 ml) is a very common event during normal pregnancy. Larger volumes of fetal blood (greater than 0.1 ml) may enter the maternal circulation at the time of delivery<sup>161, 165</sup> and as the result of various obstetric manipulations such as cesarean sec-

tion,<sup>156, 167</sup> manual removal of the placenta,<sup>127, 156, 167</sup> and perhaps the use of general anesthesia, forceps, and oxytocics.<sup>128</sup> Amniocentesis with placental injury seems to result in the transfer of unusually large amounts of blood into the maternal circulation<sup>166</sup>; this accident was observed in 4 of 13 women studied by Zipursky,<sup>168</sup> resulting in estimated losses of 10 to 50 ml of fetal blood.

### *Factors Influencing the Production of Anti-Rh Antibodies*

**SIZE OF THE TRANSPLENTAL HEMORRHAGE.** The amount of transplacental bleeding is of major importance.<sup>103, 160, 165</sup> Theoretically, sensitization of the Rh-negative mother exposed to Rh-positive cells could occur either as a result of small "normal" hemorrhages occurring during the course of pregnancy, or as a result of major bleeding occurring under the special circumstances outlined above.<sup>169</sup> Current data indicate that small transplacental hemorrhages constitute the most common cause of Rh immunization.<sup>163</sup>

One study showed that 19 of 472 Rh-negative women at risk developed antibodies within six months of delivery.<sup>163</sup> The blood of 14 of these 19 (73%) contained less than 0.1 ml of fetal cells immediately postpartum; the remaining 5 had 0.1 ml or more. Nevertheless the risk of developing antibodies is five times greater with the larger (>0.1 ml) than with the smaller (<0.1 ml) amount of bleeding—5 of 32 (15.6%) versus 14 of 440 (3%), respectively. When the transplacental hemorrhage is in excess of 3 ml, the risk of sensitization may be as high as 50%.<sup>103</sup> In addition, the same quantity of cells seems to be more immunogenic if given as a single dose, rather than a series of small doses distributed over a prolonged period, which seems to be the usual occurrence in a normal pregnancy. Why so many Rh-negative women exposed to Rh-positive cells do not develop antibodies, especially during their first pregnancy, is poorly understood. In addition to the size of the red cell inoculum and its time-dose relationship (discussed above),

other factors may be involved. Thus, a small number of Rh-negative individuals apparently do not produce detectable antibodies, even in response to relatively large Rh-positive blood transfusions. It is therefore possible that some individuals may be incapable of responding to certain Rh antigens. If true, this situation may be analogous to the genetically determined immune defects described in many animal systems.<sup>260</sup> The degree to which such failure to produce antibodies contributes to the relatively low incidence of Rh sensitization is not known.

It is also possible that sensitization may have taken place but may be undetectable by present diagnostic methods, which depend on the demonstration of fairly large quantities of antibody. This phenomenon has been termed "sensibilization"<sup>1169</sup> and, if it is valid, may explain the curious observation that antibodies are not usually seen during the first ("immunizing") pregnancy but are found during subsequent pregnancies.

**EFFECT OF ABO INCOMPATIBILITY ON RH SENSITIZATION.** In 1943, Levine noted a deficiency of ABO-incompatible matings among the parents of infants with HDN and suggested that this incompatibility afforded protection against hemolysis by anti-Rh antibodies.<sup>141</sup> Presumably, fetal cells would be destroyed by the "natural" anti-A or anti-B antibodies in the maternal circulation before sensitization to Rh could take place. It has been found, however, that this protection is not absolute, as Rh sensitization has been described across the ABO-incompatibility barrier,<sup>65</sup> although usually with low titers of anti-Rh antibody<sup>114</sup> and less severely affected infants.<sup>145</sup> Protection seems to be more complete from anti-A (90%) than from anti-B (55%),<sup>114</sup> which is in keeping with the observations that fetal B cells may survive for prolonged periods in the circulation of A<sub>1</sub> or O mothers even in the presence of anti-B antibody.<sup>58</sup> Antigenic heterogeneity of the B system similar to that of the A system (Chapter 11) has been postulated to explain these findings.

An additional factor limiting the incidence

of maternal sensitization is *Rh heterozygosity of the father*. The approximate chances of eventual sensitization to Rh by pregnancy, both with or without ABO incompatibility, are detailed in Table 27-3.

### Clinical Manifestations

The most important clinical manifestations of HDN are anemia, jaundice, hepatosplenomegaly, and, in untreated infants, bilirubin encephalopathy (kernicterus). The consequences of the disease range from death to a barely perceptible hemolytic process. The various clinical manifestations are all interdependent in terms of their genesis and the severity of their clinical expression; thus a severe degree of anemia is usually associated with equally severe hyperbilirubinemia and a high risk of central nervous system complications, whereas mild anemia will likely be accompanied by relatively less jaundice and fewer other complications.

### Anemia

Most infants suffering from HDN have good color at birth and the cord hemoglobin may only be at the lower limits of the normal range. However, the hemoglobin of most affected infants begins to fall during the first 24 hours of life, and pallor may be obvious by the second day. The degree of anemia that

**Table 27-3. Approximate Chances of Sensitization to Rh by Pregnancy under Various Conditions of Zygosity and ABO Compatibility of the Husband**

Husband's Zygosity for Rh	ABO Compatibility of Husband		ABO Type of Husband Unknown
	Incompatible (%)	Compatible (%)	
Heterozygous	1	3	2
Homozygous	4-5	11	9
Zygosity unknown	2-3	7-8	5

From Allen and Diamond <sup>34</sup> courtesy of the authors and Little, Brown & Company

develops reflects the balance between the rate of red cell destruction and production, and, in most affected infants, production is incapable of keeping up with destruction. When this imbalance becomes extreme, pallor may be very marked and may be accompanied by signs of congestive heart failure, including tachycardia, weak heart sounds, elevation of central venous pressure, massive generalized edema, ascites, pleural effusions, and marked hepatosplenomegaly. This clinical syndrome is referred to as *hydrops fetalis* and survival beyond a few hours is unusual. Indeed, most infants so afflicted die in utero, and this still constitutes the most important cause of death associated with hemolytic disease of the newborn.<sup>321</sup>

Occasionally the onset of anemia is delayed beyond the immediate neonatal period.<sup>122</sup> Under these circumstances it may be due to a slow but relentlessly progressive hemolytic process that does not require early exchange transfusions but may nevertheless lead to severe and sometimes fatal anemia after the second or third week of life. More commonly, however, despite exchange transfusions (see below), anemia of delayed onset occurs with a gradual decrease of hemoglobin levels to 5 or 6 g/dl at four to six weeks of life.<sup>122</sup> This anemia is not well understood but may be due to persistence of anti-Rh antibodies or decreased red cell production. The latter possibility is suggested by the low reticulocyte counts characteristically noted. The anemia lessens spontaneously at about eight weeks and seldom requires transfusions. Iron and vitamins, such as folic acid and vitamin B<sub>12</sub>, are of no therapeutic value.

### Jaundice

Since bilirubin is readily transferred across the placenta,<sup>96, 132</sup> most infants with HDN are not jaundiced at birth. Icterus usually develops during the first 24 hours of life; it is undoubtedly related to the loss of the placental excretory mechanism and the low level of glucuronyl transferase activity in the neonatal liver<sup>48</sup> which leads to an accumulation

of unconjugated bilirubin in the patient's blood and tissues. These functional defects may be particularly marked in premature infants<sup>45</sup> and may explain why even minimal degrees of hemolysis may lead to marked hyperbilirubinemia in these patients. In untreated infants with relatively mild disease the bilirubin level peaks by the fourth or fifth day and then declines slowly.

Since an early diagnosis of jaundice is of great clinical importance, extreme care should be taken in its detection. The baby should be examined under daylight or white fluorescent light and the skin should be blanched with a glass slide to compress the capillaries, whose pink hue obscures the yellow tinge of the jaundiced skin.

When jaundice occurs in the first 24 hours of life, it is usually due to hemolytic disease. That due to Rh antibodies must be differentiated from jaundice due to other types of antibodies,<sup>33</sup> as well as other causes of accelerated red cell destruction; these in turn must be differentiated from nonhemolytic hyperbilirubinemia occurring in the neonatal period (Table 27-2).

### Bilirubin Encephalopathy (Kernicterus)

An important complication of severe indirect hyperbilirubinemia in the neonatal period is the development of bilirubin encephalopathy.<sup>93, 112</sup> The term "kernicterus" more properly describes the macroscopic yellow staining of certain cerebral nuclei. Bilirubin encephalopathy may, of course, accompany indirect hyperbilirubinemia resulting from any cause. Initially the baby becomes lethargic and hypotonic and loses the sucking reflex, as a result of which it feeds poorly. In addition it may also roll its eyes and develop an unpleasant high-pitched cry. Later, opisthotonos and generalized spasticity are seen and at this stage most of these babies (70%) also develop irregular respirations that may be accompanied by pulmonary hemorrhage with frothy pink sputum. This may lead to death, usually within 12 hours of the onset

of pulmonary complications. Babies without pulmonary disturbances often survive for months or years but may suffer from the post-kernicterus syndrome, which includes high-frequency nerve deafness, athetoid cerebral palsy, and dental enamel dysplasia.<sup>122</sup> Surviving infants may lose some of their spasticity during the second week of life and this may lead physicians to conclude erroneously that brain damage has not occurred.<sup>107,122,123</sup> The later the onset of cerebral damage, however, the more likely is the child to live.<sup>76</sup>

There is a close relationship between the severity of the jaundice and the development of kernicterus. In one study, 8 of 11 infants with maximum bilirubin levels of 30 to 40 mg/dl developed kernicterus, whereas the corresponding incidence at bilirubin levels of 25 to 29, 19 to 24, and 10 to 18 mg/dl was four out of 12, one out of 13, and none out of 24 respectively.<sup>107</sup>

### *Hepatosplenomegaly*

Hepatosplenomegaly almost invariably accompanies hemolytic disease of the newborn and its degree reflects the severity of the underlying disease. The greatest degree of hepatosplenomegaly with accompanying ascites is seen in association with hydrops fetalis (see above). Secondarily induced hepatic damage may in turn contribute to the poor handling of bilirubin by the liver, thus introducing a vicious cycle into the pathogenetic mechanisms of this disease. Fortunately, infants who survive severe HDN seem to have no clinical or laboratory evidence of liver disease in later years.<sup>40</sup>

### *Purpura*

Purpura due to thrombocytopenia is seen in severely affected infants and is usually a bad prognostic sign. It is not clear whether the purpura is due to concomitant platelet destruction by isoantibodies or to other mechanisms, or whether it is due to decreased platelet production.

## **Laboratory Findings**

### *Blood*

Anemia, reticulocytosis, and nucleated red cells constitute the main findings in the peripheral blood. Initial determinations are usually obtained from samples of venous blood from the cord, which accurately reflect the blood findings in the infant. Only about half of all infants with hemolytic disease of the newborn have hemoglobin levels below 14 g/dl at birth,<sup>107</sup> the lower limit of normal for newborn infants<sup>121,122</sup>; indeed 11% of infants with hemolytic disease of the newborn have cord hemoglobin levels greater than 17.5 g/dl. Nevertheless, there is a rough correlation between the initial hemoglobin levels and the severity of the disease process.<sup>107</sup> In hydrops fetalis the hemoglobin concentration may be as low as 3 g/dl. Untreated patients, even those with relatively high levels of hemoglobin initially, may experience a rapid fall of the hemoglobin level after birth, often at rates of 3 g/dl or more per day.<sup>324</sup> Because of early treatment, these dramatic changes are rarely seen at the present time.

The erythrocytes are macrocytic and well filled with hemoglobin. Measurements of the red cell diameter show a biphasic curve with a macrocytic and a normocytic peak or two macrocytic peaks.<sup>150</sup> There is little poikilocytosis. Spherocytosis is usually not found in infants with HDN due to anti-Rh antibodies, although it is a characteristic feature in those with HDN due to ABO incompatibility (page 909). Polychromatophilia usually is marked. The reticulocyte count may be as high as 60%. This count (expressed as a percentage) is thought to be a poor guide to the severity of the disease or the need for transfusion therapy,<sup>107,324</sup> but studies that relate various parameters of the disease to the more meaningful absolute reticulocyte count have not been reported in the literature.

One of the most striking findings in the peripheral blood of infants suffering from HDN is the great increase in nucleated red cell precursors ("*erythroblasts fetalis*"). There may be from 10 to 100 × 10<sup>9</sup>/l nu-

cleated red cells<sup>62</sup> as compared with  $0.2$  to  $2 \times 10^9$  in normal premature or full-term infants. The nucleated cells represent all stages of maturation, although mature forms are by far the most common. They are often very large but are not megaloblastic as has been claimed by some writers.<sup>130</sup> Their size is probably a reflection of the rate of erythropoiesis.

A pronounced *leukocytosis* frequently accompanies hemolytic disease of the newborn, and counts in excess of  $30 \times 10^9/l$  have been reported.<sup>321</sup> It must be remembered, however, that the white cell count at birth may normally range between  $15$  and  $20 \times 10^9/l$ , with slightly lower counts in premature infants.<sup>121</sup> Leukocytosis is most marked in those infants who are most severely affected and are very anemic. The leukocytosis is predominantly due to an increase in neutrophils, and a considerable left shift is frequently noted.

*Platelet* counts may show normal values, but, in infants with severe disease, profound thrombocytopenia may be present.

### Serum Bilirubin Levels—

Since bilirubin is readily transferred across the placenta<sup>96,132</sup> the bilirubin levels of cord plasma do not give a complete picture of the severity of the hemolytic process. Nevertheless there is some correlation between cord bilirubin concentration and the severity of the disease. This observation may be particularly valuable when the cord hemoglobin concentration, which in most cases is a more reliable indicator of severity, is within normal limits.<sup>107</sup> Cord bilirubin values above  $4$  mg/dl are unusual and when present suggest very severe disease.<sup>122</sup>

After birth the bilirubin level reflects both the severity of the hemolytic process and the immaturity of the liver enzyme system responsible for conjugation and excretion of bilirubin. Peak bilirubin levels are usually reached by the third or fourth day of life and may attain values of  $40$  to  $50$  mg/dl.

Under most circumstances the hyperbilirubinemia is predominantly due to unconju-

gated indirect-reacting pigment. Occasionally, however, prolonged jaundice occurs in association with direct-reacting hyperbilirubinemia; this phenomenon has been referred to as the "*inspissated bile syndrome*." It may accompany a variety of clinical conditions including HDN. In one large series, the inspissated bile syndrome was present in 15% of all patients with hyperbilirubinemia.<sup>84</sup> When direct hyperbilirubinemia is present during the first 24 hours, especially in cord blood, it seems to be associated with very severe disease.<sup>122</sup> The pathogenesis of the "*inspissated bile syndrome*" is not known<sup>324</sup> and the term itself carries implications that may be incorrect.

Only unbound bilirubin is toxic to the central nervous system.<sup>119</sup> Indirect-reacting bilirubin readily associates with albumin in the circulation and therefore estimation of the binding capacity of albumin for bilirubin is of critical clinical importance. Since phenolphthalein (PSP) appears to compete with bilirubin for binding sites on albumin, the PSP binding capacity of serum may be used as a measure of the ability of albumin to bind additional bilirubin.<sup>132</sup> An inverse relationship between serum bilirubin levels and PSP binding capacity has been established, and this is used as an index of the need for exchange transfusions.<sup>133</sup> When the PSP technique is not available, the simple determination of albumin or total serum protein concentrations may be of value.

### Serologic Findings ✓

A positive reaction to the direct antiglobulin test given by cord blood erythrocytes is the characteristic finding in hemolytic disease of the newborn due to anti-Rh antibodies. The reaction is positive with anti-Ig sera only. Its strength may vary considerably, however, and occasionally the reaction may be negative when the test is performed by ordinary techniques, even when incomplete antibodies are found in the maternal serum.<sup>321</sup> On the other hand, the coating of red cells by antibody may sometimes be so heavy as to block the Rh antigenic sites and

interfere with Rh typing. In such cases, Rh positivity must be inferred from the strong reaction to the direct Coombs' test.<sup>122</sup> Without therapy the antiglobulin reaction may remain positive for several weeks, but will gradually become weaker; when infants are effectively treated with exchange transfusions, the reaction quickly becomes weak or negative.

Most infants with positive reactions in direct antiglobulin tests also have free antibodies in the serum at the time of birth.<sup>324</sup> These antibodies may be demonstrated by the indirect antiglobulin test.

### Antenatal Assessment of Severity

Proper prevention and therapy of HDN depend on the prenatal demonstration of biochemical, serologic, and clinical changes, both in mother and fetus.

### Serologic Changes in the Mother

Maternal Rh sensitization and HDN are rare during the first pregnancy, unless the mother has previously been sensitized by transfusion with Rh-positive blood. Antibodies are frequently detectable about six to eight weeks after the first sensitizing pregnancy, probably in response to the transfer of a large number of fetal cells into the maternal circulation at the time of delivery (page 896). Initially IgM saline reactive antibodies are produced that do not cross the placenta. Although these antibodies are of no direct significance to the fetus, even during pregnancy, they may herald the advent of IgG antibodies. These usually replace IgM antibodies if the antigenic stimulus is continued or renewed. Their concentration remains low, however, until a booster stimulus of fetal red cells leads to a further rise in antibody titer, usually during the third trimester of a subsequent pregnancy. Because of this pattern it has been found useful to obtain a baseline titer at about 16 weeks' gestation, a second determination at 28 to 32 weeks, and subsequent titers at intervals of one to four weeks, depending upon the rate of increase in anti-

body concentration.<sup>122</sup> Unfortunately, although there is a rough general correlation between maternal antibody titers and the severity of the hemolytic process in the infant,<sup>61,90,109,155,164</sup> especially during the first affected pregnancy,<sup>136</sup> exceptions to this general pattern do not allow complete reliance on maternal antibody titers alone.<sup>109,150</sup> Nevertheless, maternal antibody titers furnish a useful index of the baby's prognosis in the majority of patients.

The accuracy of predicting the outcome of a given pregnancy can be increased considerably if, in addition to measuring maternal antibody levels, the individual's family pattern, and particularly the severity of the disease in the first affected infant, is taken into account.<sup>150</sup> Chown<sup>95</sup> published data listing four grades of severity and the corresponding predictions of severity in the next affected child.

### Amniotic Fluid Examination

Amniotic fluid, which is normally colorless or the color of pale straw, may become bright yellow when severe HDN is present. The total composition of the pigment has not yet been determined but much of it appears to be bilirubin,<sup>104</sup> probably derived from fetal red cell heme. Neither is it known how the pigment enters the amniotic fluid from the plasma of the fetus.<sup>107</sup>

The total amount of amniotic pigment, as reflected by optical density measurement at 450 nm, correlates well with the severity of the anemia at birth,<sup>99</sup> as well as with the fetal outcome.<sup>39,100</sup>

The concentration of pigment in the amniotic fluid is usually measured by spectral photometry over the range of 350 to 700 nm (Fig. 27-2). The optical density of normal amniotic fluid describes a straight line over the range of 350 to 600 nm, but when pigment is present the so-called "bilirubin bulge" is seen with a peak at 450 to 460 nm.<sup>46</sup> The increased optical density at the peak can be estimated by joining the straight parts of the curve and determining the height of the bulge above the conjectural baseline. Impor-

Fig. 27-2 Optical density curve of amniotic fluid obtained from an isosensitized woman. Normally a straight line is seen between 350 and 600 nm. The height of the "bilirubin bulge" is measured at 450 nm. The value obtained here (0.206) falls into zone 3 given a gestational age of 34.5 weeks (Fig. 27-3) (From Bowman and Pollock,<sup>46</sup> courtesy of the authors and Pediatrics.)

tant sources of error include (1) contamination with fetal blood, which may contribute bilirubin; (2) hemolyzed red cells of fetal or maternal origin that yield a false rise in optical density; (3) contamination with meconium or vernix caseosa that causes turbidity and interferes with optical density readings; and (4) exposure to light, which reduces pigment concentration by oxidation.<sup>122</sup> Since the optical density of normal as well as abnormal amniotic fluids tends to fall with advancing gestation,<sup>99</sup> it is important to interpret optical density data in the light of this knowledge. This is illustrated in Figure 27-3 in which the increase in optical density, corrected for gestational age, is roughly divided into three

zones indicating the approximate degree of fetal affliction.<sup>46</sup> A stationary or rising optical density measurement in repeated samples indicates worsening of the hemolytic process.

Although optical density measurements are most commonly employed in the examination of amniotic fluid, other techniques also have been recommended. Thus, amniotic fluid bilirubin levels may be measured biochemically, but since very low concentrations of bilirubin are often significant, special techniques are necessary.<sup>75,117</sup> Blood-stained specimens cannot be used for optical density measurements,<sup>120</sup> but if such samples contain fetal cells, the latter may be typed: if they are Rh negative, additional studies are unnecessary.<sup>47</sup>

The determination of bilirubin-protein ratios is useful,<sup>53,112,116</sup> since these are independent of the time of gestation and may also allow for variations in liquor amnii volume that may seriously affect pigment concentration. Indeed, the protein concentration of amniotic fluid is itself an excellent guide to the severity of the disease.

The concentration of anti-Rh<sub>0</sub> antibody in the amniotic fluid also appears to correlate well with the severity of the hemolytic process,<sup>72,135</sup> although this has been denied by some.<sup>72</sup> When used in conjunction with spectrophotometric techniques, it enhances considerably the accuracy of prediction.<sup>72</sup> The pathway by which the anti-Rh<sub>0</sub> enters the amniotic cavity is not known. When mothers with high concentrations of anti-Rh<sub>0</sub> carry a

Rhesus-negative infant, virtually no antibody appears in the amniotic fluid.<sup>72</sup>

*Technical details* of the collection, preparation, and examination of amniotic fluid are provided in several reviews.<sup>46,99,100</sup> When carried out by an experienced operator, the procedure seems to be fairly safe, and major complications are rare. Nevertheless, occasional cases of hemorrhage, including fetal exsanguination, and infection have been reported.<sup>122</sup> Placental trauma, with hemorrhage into the maternal circulation, appears to be a particularly common problem and may increase antibody production by the mother.<sup>165,168</sup> It is therefore most important to localize the placenta accurately before amniocentesis, either by ultrasound techniques or, if necessary, by isotopic methods.<sup>122</sup>

Fig. 27-3. Plotting the height of the bilirubin bulge (increased optical density at 450 nm—see Fig. 27-2) against gestational age. Three zones of severity are indicated: Zone 1, Rh-negative infant or mildly affected Rh-positive infant; Zone 2, intermediate disease; Zone 3, severe disease and impending fetal death. The value obtained from Figure 29-2 falls into Zone 3, given a gestational age of 34.5 weeks. (From Bowman and Pollock,<sup>46</sup> courtesy of the authors and Pediatrics.)

## Treatment

Optimal management of the sensitized mother and her Rh-positive infant requires continued antenatal and postnatal care of both infant and mother by a team of obstetricians, pediatricians, and serologists.<sup>122</sup> While antenatal care is focused on the diagnosis and therapy of severe anemia and hydrops fetalis, which constitute the two most important threats to fetal life, postnatal care is mainly concerned with the prevention of damage due to hyperbilirubinemia and severe anemia in the infant, and the suppression of anti-Rh antibody production in the mother.

## Prenatal Management

Proper antenatal care of the erythroblastic infant has to be based on considerations discussed in earlier sections, namely, (1) the birth order of the child; (2) maternal history in regard to the outcome of previous pregnancies, blood transfusions, etc.; (3) serologic tests including the maternal antibody titers and the father's Rh zygosity; and, finally, (4) the results of amniotic fluid examinations. On the basis of these considerations, three major courses of action are open to the obstetrician caring for an Rh-sensitized pregnant mother:

1. If the results of all tests and the historical considerations are favorable, the physician may decide to do nothing or to use controlled labor at 38 weeks.
2. If, on the other hand, there appears to be great risk of hydrops fetalis or stillbirth during the late stages of pregnancy, earlier induction between 34 and 38 weeks may be indicated.
3. Finally, if there is risk of hydrops fetalis or stillbirth before 34 weeks, intrauterine and intraperitoneal transfusions followed by induction of labor at 34 weeks become mandatory.

**EARLY INDUCTION OF LABOR.** When early delivery is not required for other reasons, routine "preterm" induction at about 38 weeks of gestation offers some undeniable advantages, including the ability to assemble

a well-prepared and coordinated team of obstetricians, pediatricians, and technical staff, an undertaking that may be more difficult during spontaneous, middle-of-the-night deliveries.<sup>122</sup>

In the more severely affected infants, premature delivery is induced at 34 weeks in order to decrease the incidence of stillbirths due to anemia, since about half the intrauterine deaths take place after the thirty-fourth to thirty-fifth weeks of pregnancy.<sup>35,153</sup> The decision to proceed with early induction is based primarily on the results of amniocentesis (above) and, to a lesser degree, on clues provided by the previous history<sup>56</sup> and antibody titers. A policy of premature induction of labor based on amniocentesis findings can lead to a drop in the stillbirth rate and a considerable drop in the neonatal death rate.<sup>102</sup>

**INTRAUTERINE TRANSFUSION.** At least half of the intrauterine deaths occur before the thirty-fourth week of gestation. Premature induction of labor cannot save these babies since the risk of death from causes related to prematurity is considerable, even in the absence of complicating diseases such as HDN: 15% at 34 weeks, 30% at 32 weeks, and 60% at 30 weeks.<sup>107</sup> When prematurity is complicated by HDN, the mortality rate must certainly be considerably higher.<sup>107</sup> The main threat to survival of these infants *in utero* is anemia. The success of intrauterine transfusions<sup>101,102</sup> depends on the fact that red cells introduced into the peritoneal cavity of the fetus find their way into the circulation through the thoracic duct and survive normally.<sup>102</sup> The technique should be undertaken only by an experienced obstetric and pediatric team.<sup>122</sup> Accurate localization of the placenta is mandatory. The volume and frequency of transfusion vary with the gestational age, 30 to 100 ml of packed red cells being administered every two to three weeks until the baby is delivered at 34 to 35 weeks of gestation. With successful transfusions the amount of adult hemoglobin in cord blood should be of the order of 55 to 95% instead

of the usual proportion of 15 to 40%.<sup>122</sup> Complications include trauma to the fetus, trauma to the placenta, infection in mother and fetus, and onset of premature labor.<sup>148</sup> Two cases of suspected graft-versus-host disease have also been described and are presumably attributable to the transfer of incompatible lymphocytes into an immunologically immature recipient.<sup>148</sup>

While some babies are undoubtedly saved by intrauterine transfusions, the overall results are discouraging: stillbirths still occur in 48 to 55% of those thus treated and 13 to 32% of those born alive die in the neonatal period, leaving an overall survival rate of only 35 to 40%.<sup>148</sup> Complications in live-born babies include unexplained reticulocytopenia, an unusually high incidence of the "inspissated bile syndrome," and hypoglycemia. In addition, the neonatal death rate may be seven times as high as that of infants with hemolytic disease who are delivered spontaneously.

### Postnatal Management

**EXCHANGE TRANSFUSIONS.** The first exchange transfusion for HDN was performed in Canada in 1925,<sup>81</sup> but no attention was paid to this novel approach to therapy until almost 20 years later when a similar procedure was popularized by Wallerstein,<sup>149</sup> Wiener,<sup>154</sup> Diamond,<sup>63</sup> and Mollison,<sup>108</sup> among others. The results of exchange transfusions since then have been extremely gratifying and the mortality of live-born affected infants has been greatly reduced as a direct result of this therapy.<sup>36,107,110,324</sup>

The objectives of exchange transfusions include: (1) the removal of antibody-coated red cells from the circulation of the infant; (2) the correction of anemia and the reversal of congestive failure in hydropic or prehydropic infants; and, later, (3) the removal of bilirubin.

Since about 85% of antibody-coated red cells may be removed by the initial exchange transfusion, the number of red cells at risk can be reduced considerably and the subse-

quent production of bilirubin is greatly curtailed (each gram of hemoglobin from hemolyzed red cells yields 35 mg of bilirubin, Chapter 5). Thus, an exchange transfusion carried out within a few hours of birth not only forestalls the development of severe anemia but also greatly reduces the chance of kernicterus.<sup>107</sup>

Infants born with severe anemia are almost always in cardiac failure. While these infants urgently require red cells, simple transfusion is very dangerous since it inevitably makes congestive failure worse. Exchange transfusion, during which a greater volume of blood is removed than is injected, is the only safe alternative. In these infants, packed red cells are used instead of whole blood. The venous pressure is monitored throughout the procedure by measuring the level to which the blood rises in the umbilical vein catheter.<sup>63</sup>

One complete exchange transfusion (200 ml/kg) also removes about 90% of the plasma bilirubin. However, the extravascular pool of this pigment is much greater than the intravascular pool, and reequilibration occurs within 30 minutes.<sup>140</sup> This accounts for the "rebound hyperbilirubinemia" noted after the exchange, with final plasma concentrations of 40 to 60% of the initial level.<sup>49,140</sup> Because extravascular and intravascular bilirubin equilibrate rapidly, the final size of the bilirubin pool depends, at least in part, on the length of time taken to make the exchange, which should probably never be less than 90 minutes.<sup>107</sup>

Indications for exchange transfusions vary widely among different workers. The information needed and the criteria that are applied in arriving at a reasonable decision are summarized in Table 27-4. In addition, a graph of serum bilirubin levels plotted against the infant's age, such as that prepared by Allen and Diamond,<sup>122</sup> is helpful in anticipating the need for further exchange transfusions in the hyperbilirubinemic infant.

The technique of exchange transfusion has been described.<sup>107,120,122</sup> The umbilical vein is the most preferable route of exchange. One hundred and sixty to 200 ml/kg is exchanged

**Table 27-4. Need for Exchange Transfusion in Infants with a Positive Coombs' Reaction—Suggested Course of Action**

<i>Findings</i>	<i>Observe</i>	<i>Consider Exchange</i>	<i>Do Exchange</i>
<b>At Birth</b>			
History or course of action in previous offspring was	No exchange transfusion	Exchange transfusion was necessary or kernicterus was observed	Death or near death from erythroblastosis
Maternal RH antibody titer	< 1:64	> 1:64	
Clinical situation	Apparently normal	Induced or spontaneous delivery of premature infant	Jaundice, fetal hydrops
Cord hemoglobin	> 14 g/dl	12–14 g/dl	< 12 g/dl
Cord bilirubin	< 4 mg/dl	4–5 mg/dl	> 5 mg/dl
<b>After Birth</b>			
Capillary blood hemoglobin	> 12 g/dl	< 12 g/dl	< 12 g/dl and falling in first 24 hours
Serum bilirubin	< 18 mg/dl	18–20 mg/dl	20 mg/dl in first 48 hours or 22 mg/dl on two successive determinations at 8 to 8-hour intervals after 48 hours
			Clinical signs suggesting kernicterus at any time or at any bilirubin level

From McKay<sup>104</sup> courtesy of the author and Pediatrics

over a period of at least 90 minutes. Heparinized blood is preferable because of the potential complications of the acid citrate dextrose anticoagulant, although the latter is usually more readily available. The blood should be fresh in order to assure high 2,3DPG levels in the red cells (Chapter 11) and in order to minimize the dangers of hyperkalemia and acidosis inherent in the use of older blood. It should be O Rh negative and should always be cross-matched against the mother's serum by the indirect Coombs' test, preferably prior to delivery. When indicated, the cross-match procedure should include a sickle cell test (Chapter 25) of the donor blood.

Since damage to the central nervous system is primarily attributable to free indirect-reacting bilirubin, that is, pigment unbound to albumin, it has been found advantageous to add albumin to the exchange transfusion,

particularly when given to severely jaundiced babies.<sup>120,153</sup> The usual dose is 1 g/kg. Albumin is *not* to be used in infants with hydrops fetalis. It has been suggested that phototherapy may reduce the requirements for exchange transfusion in some patients.<sup>129</sup>

*Complications*<sup>122</sup> include (1) the *biochemical changes* of hyperkalemia due to the use of old blood; hypocalcemia, increased blood citrate levels, and acidosis due to the use of ACD stored blood; (2) the *cardiovascular complications* of air or blood-clot emboli, septic thrombosis, volume overload, and cardiac arrest, the latter primarily due to factors listed under (1); (3) *clotting defects*, especially those due to overheparinization or thrombocytopenia<sup>52,107</sup>; and (4) *bacteremia and serum hepatitis*.<sup>89a</sup> The mortality rate directly attributable to exchange transfusion should be less than 1%.<sup>107</sup>

## Prevention of Rh Hemolytic Disease

The most effective means of protecting infants against Rh hemolytic disease are those that prevent maternal sensitization to fetal Rh antigens or inhibit the production of antibodies specific for those antigens. Two methods are available<sup>165,166</sup>: (1) by preventing large transplacental hemorrhages that expose patients to the high risk of immunization, and (2) by passive immunization of Rh-negative mothers with anti-Rh antibodies. The former can be accomplished by meticulous obstetric care and particularly by the elimination of maneuvers that disturb the chorionic site, including cesarean section, manual expression of the placenta, and needling of the placenta during amniocentesis.

A concept for the prevention of Rh immunization by passive administration of Rh antibodies<sup>70,73</sup> evolved from the observation that (1) immune responses could be blunted considerably by the concomitant administration of specific antibodies<sup>134,138</sup> and (2) Rh immunization rarely resulted from a pregnancy in which the fetal erythrocytes were ABO incompatible with the mother's serum.<sup>141</sup> The hypothesis was first tested in Rh-negative volunteers who received Rh-positive blood by injection.<sup>159,165</sup> It was clearly shown that the concomitant administration of anti-Rh antibodies could bring about a ten-fold reduction in the incidence of sensitization (three out of 78 vs 29 out of 75).<sup>165</sup> Similarly spectacular results were subsequently achieved in well-controlled studies<sup>125</sup> in which the incidence of sensitization in high-risk women who received anti-Rh gamma globulin within 72 hours postpartum was compared with that of high-risk women who received no such therapy—none of 75 antibody-protected women developed antibodies, whereas 19 of 78 unprotected mothers did. Clinical trials involving *all* women at risk confirmed these findings.<sup>57,67,159,162,166</sup> In addition to the lack of antibodies six months postpartum, the incidence of antibody production during the

next pregnancy also was greatly reduced.<sup>57</sup> Indeed the point has been made that protection must not be considered complete until these women have gone through another pregnancy and have remained free of antibodies.<sup>165</sup>

Although the risks of immunization with *abortion* may be less than that associated with normal termination of pregnancy<sup>44,115,159</sup> they are nevertheless considerable.<sup>45,74,159,166</sup> It is therefore advisable to give Rh prophylaxis to *all* women who abort unless the sire is known to be Rh negative.

*Standard prophylaxis* consists of 300 µg of anti-Rh<sub>0</sub> (D) antibody given intramuscularly to the unsensitized Rh-negative woman within 72 hours of delivery of an Rh-positive infant. Some European centers have given smaller amounts of a more highly purified preparation intravenously, with excellent results.<sup>44</sup> Indeed, much faster elimination of Rh-positive cells from the maternal circulation<sup>42,159</sup> and a much lower incidence of failures (one out of 3,695) have been reported with intravenous prophylaxis than with intramuscular.<sup>159</sup> If these studies can be confirmed, the intravenous route of antibody administration may find much wider application in the future.

Standard prophylaxis may be insufficient to deal with *massive* transfusions of Rh-positive cells of either fetal or donor origin.<sup>44,159,166</sup> Since the number of women experiencing a major (>30 ml) transplacental hemorrhage may approach 1%,<sup>166</sup> routine screening procedures for the detection of large amounts of bleeding are necessary. Doses of 10 to 25 µg anti-Rh<sub>0</sub> antibody/ml of Rh-positive red cells in the maternal circulation have been recommended.<sup>44</sup> Clearance and protection studies carried out in male volunteers suggest that these doses probably are adequate. Such large quantities of gamma globulin should always be given intramuscularly.

When adequate doses of antibodies are used, protection against Rh immunization is *virtually* complete.<sup>166</sup> A small number of primigravidae (1.7%<sup>56</sup>) may develop antibodies *during* their first pregnancy, however,

and under these circumstances postpartum prophylaxis would be useless.<sup>168</sup> Whether such sensitization can be prevented by the routine use of anti-Rh globulin antepartum remains to be seen. Since IgG antibodies readily cross the placenta, the administration of anti-Rh globulin to a pregnant woman is not without potential risk to the fetus, but to date no harm has come to babies whose mothers were so treated.<sup>41,169</sup>

Rh-immune globulins are produced from the plasma of artificially immunized male volunteers or from highly sensitized Rh-negative women who may be hyper-immunized by injection of Rh-positive cells if they can no longer bear children.<sup>41</sup> Many produce antibody levels in excess of 100  $\mu\text{g}/\text{ml}$  serum, although levels in the range of 30 to 100  $\mu\text{g}/\text{ml}$  are more common. The sera are usually obtained by weekly plasmapheresis (600 to 700 ml) of these donors without apparent harm over prolonged periods.

The way in which anti-Rh antibody brings about specific suppression of the anti-Rh immune response is still under active investigation. To date, three main possibilities have been considered,<sup>159</sup> namely, (1) that immunosuppression is due to the destruction of the antigen, or its shunting, from sites where sensitization could take place to areas in the reticuloendothelial system that are immunologically naive (this possibility is exemplified, for instance, by the protection afforded by ABO incompatibility); (2) that it is due to the blocking or binding of antigenic determinants so that effective contact with antigen-sensitive cells is prevented; or (3) that it is due to a direct suppressive effect of antibody on the antigen-sensitive cells themselves.

## Hemolytic Disease of the Newborn (HDN) Due to ABO Incompatibility

### Pathogenesis

Hemolytic disease of the newborn due to

ABO incompatibility results from the interaction of maternal anti-A or anti-B antibodies with fetal erythrocytes carrying the corresponding blood group antigens. While HDN due to ABO incompatibility is about twice as common as that due to Rh incompatibility, it is rarely as severe and often goes unnoticed, its mild clinical manifestations blending deceptively into the bilirubin-tainted landscape of neonatal physiology.

Statistically, about 20% of all pregnancies involve ABO incompatibilities of the type that could lead to HDN,<sup>37</sup> but the incidence of significant hemolytic disease is only one in 150 births, and about one in five babies at risk develop jaundice.<sup>107</sup> Moreover, while several patterns of maternal-fetal ABO incompatibilities are possible, virtually all hemolytic disease occurs in A or B infants of group O mothers. This curious phenomenon is attributable to the nature of the anti-A or anti-B antibodies: only group O mothers produce sufficient quantities of IgG anti-A or anti-B antibodies, the corresponding antibodies of group A or B mothers being confined to the IgM variety which cannot cross the placental barrier (page 312).

Since group O individuals are "naturally" presensitized to A and B antigens by exposure to ABO-like substances found in food and other exogenous sources, first-born infants are affected as frequently as those born subsequently. Indeed, even when the first infant has suffered from HDN, other incompatible siblings may or may not have the disease, there being no predictable increase in the severity of the hemolytic process in succeeding siblings as occurs in Rh hemolytic disease.

The ability of secretor (Chapter 11) infants to produce soluble blood group substances does not appear to protect them against ABO hemolytic disease.<sup>107</sup> This may be due to the fact that IgG antibodies are more difficult to neutralize by soluble blood group substances than are IgM antibodies.<sup>92</sup> Indeed, the ratio of secretor to nonsecretor babies is slightly higher than expected,<sup>143</sup> leading to the suggestion that the secreted blood group substances may play a role in sensitization.

## Clinical Manifestations

The most common manifestation of ABO hemolytic disease is jaundice. Like that of Rh hemolytic disease, it appears during the first 24 hours of life but is not as pronounced; it very rarely is sufficiently severe to cause complications such as kernicterus. The anemia is correspondingly mild, pallor is uncommon, and hydrops fetalis is exceedingly rare. Mild degrees of hepatosplenomegaly may be observed.

## Laboratory Findings

In keeping with the clinical manifestations, the hemoglobin is usually normal, but on occasion it may drop as low as 10 g/dl. The blood smear shows evidence of compensatory erythropoiesis with polychromatophilia and a few nucleated red cells. The reticulocyte count is appropriately elevated. Spherocytes, which are not seen in Rh hemolytic disease, may be a striking feature of the peripheral smear.

Elevated serum bilirubin values frequently constitute the only laboratory evidence of hemolysis, and, as in Rh hemolytic disease, the indirect-reacting fraction is predominantly elevated (page 900).

## Serologic Findings

The infant's red cells often give a negative or only weakly positive reaction to the direct antiglobulin test, even though A or B specific antibodies, which interact strongly with fetal or adult cells *in vitro*,<sup>82,143</sup> can be eluted.<sup>60</sup> This failure of antibody-sensitized fetal cells to agglutinate with antiglobulin sera may be a function of the smaller number of antibody molecules sensitizing these fetal cells<sup>131</sup> which in turn may, at least partially, reflect the greater distance between sites in fetal cells as compared to the distance in adult cells.<sup>144</sup>

Various modified techniques have been devised in an effort to improve the detection of sensitized cells.<sup>107</sup> While some give better results than others, none gives the strong, reliable antiglobulin reaction seen with Rh hemolytic disease.

Free antibody against adult cells frequently

is demonstrable in the infant's serum and, when it has specificity for the infant's A or B antigen, the presence of ABO hemolytic disease must be presumed. Reactions to the *indirect* Coombs' test were found to be positive in 39 of 42 jaundiced ABO-incompatible infants when the tests were performed during the first 24 hours following birth.<sup>79</sup> Complement is not found on the red cells of babies suffering from ABO hemolytic disease<sup>151</sup> and the complement titers of these babies are normal,<sup>151</sup> suggesting that the mechanism of hemolysis is complement independent and perhaps akin to that of Rh HDN (page 894).

## Antibodies in the Maternal Serum

In some ABO-incompatible pregnancies, other immune properties are found in mothers' serum, including the presence of hemolysins and agglutinins that are difficult to neutralize with A and B substances, and that react with group A pig cells.<sup>71,92,107</sup> However, only one of three infants born of mothers with such antibodies shows hemolytic disease. Since only non-inhibitable 7S antibodies are associated with disease, a better correlation between the presence of antibodies and hemolytic disease could be expected if IgG antibodies were separated from the IgM antibodies. A relatively simple test that seems to fulfill these requirements has been devised<sup>124</sup>; a high titer ( $> 1000$ ) was found in 13 of 18 infants requiring exchange transfusions, in four of 50 who did not require exchange transfusions, and in one of 16 healthy, incompatible infants.

## Treatment

Severe anemia is very uncommon and therapy, when necessary, is therefore directed toward control of hyperbilirubinemia. Phototherapy is very useful for this purpose.<sup>89,133</sup> Exchange transfusion with whole blood should be carried out when the bilirubin level threatens to exceed 20 mg/dl. Group O blood of the infant's Rh type should be used, although O cells suspended in AB plasma would theoretically be preferable.<sup>107</sup> Some authors, however, do not consider the use of

AB plasma worthwhile.<sup>77</sup> If the use of AB plasma is not practicable, donors with low anti-A or anti-B hemolysin titers should be used. The principles and methods of exchange transfusion are otherwise the same as those for Rh hemolytic disease.

## Immuno-hemolytic Anemias Due to Warm Reactive Antibodies

Immuno-hemolytic anemias due to warm reactive autoantibodies (*autoimmune hemolytic anemias*, AIHA) readily fall into three broad categories<sup>217</sup>: (1) those in which the hemolytic anemia dominates the clinical picture and seems to be unaccompanied by other coexisting or underlying disease ("idiopathic" or "primary"); (2) those in which the hemolytic process is closely linked to some other well-defined disease ("symptomatic" or "secondary"); and (3) those immuno-hemolytic anemias clearly associated with exposure to drugs or chemicals. The first category is to be regarded as a convenient temporary grouping and will eventually be eliminated through increased understanding of basic pathogenetic mechanisms. For purposes of this discussion it is convenient to deal with the first two categories as a unit; the drug-induced hemolytic anemias will be considered separately below. The diagnostic approach to the patient with hemolytic anemia is discussed in Chapter 20 (page 737).

### Etiology and Pathogenesis

Warm reactive antibodies with specificity for red cell antigens have been described in association with a number of diseases (Table 27-5), including viral infections, malignant conditions, immune deficiency states, and as part of other diseases with "autoimmune"

**Table 27-5. Autoimmune Hemolytic Anemias (AIHA)**

<b>I. Warm reactive antibodies</b>	
<input checked="" type="checkbox"/> A	Primary or idiopathic, without obvious cause
<input checked="" type="checkbox"/> B	Secondary or symptomatic, associated with
1	Chronic lymphocytic leukemia
2	Lymphoma
3	Non-lymphoreticular tumors
4	Autoimmune diseases, especially lupus erythematosus
5	Viral infections
<b>C</b> Drug-dependent antibodies	
1	Penicillin type
2	Stribophen type
3	Alpha methyl dopa type
<b>II. Cold reactive antibodies</b>	
<input checked="" type="checkbox"/> A	Primary cold agglutinin disease
<input checked="" type="checkbox"/> B	Secondary cold agglutinin disease, associated with
1.	Infections: M. pneumoniae, infectious mononucleosis
2	Lymphoreticular neoplasms
<input checked="" type="checkbox"/> C.	Paroxysmal cold hemoglobinuria
1	Idiopathic
2	Secondary
a	Syphilis
b.	Viral infections, especially measles, mumps

features, such as systemic lupus erythematosus. Many theories have been proposed to explain the production of antierythrocyte antibodies under such circumstances. These include (1) alterations in the patient's erythrocytes that make surface antigens no longer recognizable as self; (2) disturbances of immune responsiveness, including the emergence of forbidden clones; and (3) genetically determined peculiarities of immune responsiveness that lead to cross-reactivity of normal immune responses with the patient's own tissues.

Although erythrocyte surfaces can be damaged by viruses in vitro and new antigens can be uncovered by enzymatic damage to red cells,<sup>217</sup> there is insufficient clinical evidence to suggest that this actually occurs in vivo or that human erythrocytes damaged in some way become antigenic. In this context it is particularly important to emphasize that many of the red cell autoantibodies actually interact with *normal* antigenic determinants,

\*"Autoimmune" is used as a convenient descriptive term only. It signifies the presence of immunologic processes with specificity for antigens found on the tissues of the individual making the immune response. The term is not intended to convey any implication as to mechanisms, as, for example, the emergence of "forbidden clones."

particularly those belonging to the Rh group of antigens.

The concept of autoimmunity as the result of disturbed immune mechanisms implies a loss of fetally acquired tolerance towards erythrocyte autoantigens. This fundamental defect is thought to develop in immunologically competent cells as a result of somatic mutation<sup>210,211,219</sup> with the emergence of new clones of antibody-producing cells that no longer recognize certain antigens as "self." This concept is thought to derive support from the association of autoimmune hemolytic anemias with recognizable disorders of the lymphoid system and with diseases having other autoimmune manifestations.<sup>286</sup> It should be pointed out, however, that such associated disorders could equally well have arisen as the result of some other cause common to both disorders, such as viral infection. Indeed, there is no direct evidence to support the contention that autoimmune disease ever results from specifically acquired derangements in immune responsiveness.

Occasionally, autoimmunity seems to be the result of a normal immune response toward a foreign antigenic determinant that cross-reacts with an autologous tissue constituent. This has been observed, for example, in a patient suffering from chronic phenacetin ingestion; in time this patient produced anti-phenacetin antibodies that also reacted against an autoantibody found on the patient's own red cells.<sup>246</sup> Similarly some strains of mycoplasma are thought to have antigenic determinants similar to the I antigen of human red cells,<sup>285,386</sup> resulting in the formation of cold agglutinins cross-reacting with all erythrocytes carrying this antigen. Although this claim has not been confirmed by others,<sup>235</sup> sufficient evidence of cross-reactivity exists in other forms of autoimmune disease<sup>300</sup> to maintain it as an attractive hypothesis.

In some autoimmune phenomena the destruction of autologous tissues may simply be the result of close proximity between a foreign antigenic determinant and normal tissues caught in the immune attack as "innocent bystanders." This mechanism has been docu-

mented in some drug-induced immunohemolytic anemias (see below), in certain "slow-virus" infections,<sup>262,274</sup> and in graft-versus-host disease.<sup>231</sup>

One of the most promising concepts of autoimmunity is derived from animal studies that link genetic factors and persistent viral infections, on the one hand, with autoimmune phenomena, including Coombs'-positive hemolytic anemia, on the other.<sup>262</sup> NZB mice appear to pass murine leukemia virus vertically from generation to generation and seem incapable of eliminating the virus until late in the lifetime of infected animals.<sup>207,262</sup> By midlife, virtually all mice of this strain have Coombs'-positive hemolytic anemia, the majority have membranous glomerulonephritis, and some develop malignant lymphomas and sarcomas. It is particularly noteworthy that the development of a positive reaction to the Coombs' test in NZB mice corresponds closely in time to the production of specific virus-derived soluble antigen. Immunologic maneuvers that inhibit the appearance of soluble antigen also inhibit the appearance of Coombs' positivity, whereas manipulations that aid the early proliferation of the virus also accelerate the appearance of anti-red cell antibodies.<sup>207,262</sup> Antibodies eluted from affected red cells interact equally well with normal mouse erythrocytes irrespective of strain,<sup>257</sup> suggesting that the antibodies are not directed against virus-modified red cell antigens adhering to the red cell surface. These findings strongly suggest a direct link between leukemia-like viral infection and the development of immune hemolytic anemia in NZB mice. They may also illuminate several observations made in regard to human immunohemolytic disease; eg, the frequent association of "idiopathic" Coombs'-positive hemolytic anemias with immune deficiency states, both general and restricted (Chapter 44), thymic disorders,<sup>263</sup> chronic virus infections,<sup>301</sup> lymphomas,<sup>277</sup> and various other autoimmune phenomena,<sup>219,286</sup> including systemic lupus erythematosus. It is also noteworthy that the development of autoimmune manifestations in NZB mice appears to be under some sort of genetic control.

## Incidence

Autoimmune hemolytic anemias are not confined to any particular race although most published reports have dealt with Caucasian patients.<sup>217</sup> While it has generally been thought that there is no genetic basis for the disease, recent observations in man<sup>237,278,295</sup> and animals<sup>260</sup> suggest that a reevaluation of these views may be worthwhile (see also page 911). An increasing number of human cases of autoimmune hemolytic anemia in which a familial incidence is clearly demonstrable are being reported.<sup>219</sup> The disease is found in members of both sexes, but an excess of cases in females has been reported, particularly the "idiopathic" type of disease.<sup>219</sup> Subjects of all ages are affected. There seems to be an increased number of cases of "symptomatic" or "secondary" autoimmune hemolytic anemia of the warm antibody type in patients over 45, whereas the number of idiopathic cases is fairly evenly distributed throughout life.<sup>219</sup>

## Clinical Manifestations

The onset and course of autoimmune hemolytic anemia (AIHA) of the warm antibody type are most variable; the hemolytic process may be so mild as to be barely discernible by erythrocyte survival studies or it may be fulminant and life-threatening. Hemolysis of gradual and insidious onset frequently is seen in association with malignant disease or lupus erythematosus, whereas explosive and life-threatening hemolytic episodes seem particularly common when autoimmune hemolysis accompanies acute viral infections or when the underlying cause is obscure, especially in children.<sup>217</sup> The duration of the disease also varies considerably; although occasionally the episodes are short-lived, especially when hemolysis complicates acute infectious processes, the course is more commonly chronic and intractable. When the autoimmune hemolysis accompanies disorders such as Hodgkin's disease or other lymphomas the hemolytic process may wax or wane with the underlying disease.

Symptoms are most commonly related to the anemia and in patients with mild or chronic disease may include undue fatigue, dyspnea on exertion, and palpitation. When the hemolytic process is acute and massive the anemia may be so fulminantly progressive as to lead to shock-like prostration and semi-coma.<sup>217</sup> Sometimes jaundice is the patient's first complaint, but this is a variable symptom. When the disease is of acute onset and very severe, hemoglobinuria may be noted. Unexplained fever and abdominal pain occur often enough to be selectively noted.<sup>245</sup> Other less common symptoms include thrombophlebitis, precordial pain, and headache.<sup>217</sup> Additional symptoms may point to underlying disease. The history should always include detailed information concerning the drugs taken by the patient (see page 916). Pertinent physical findings include pallor and jaundice, which in severe cases may be accompanied by a peculiar cyanosis of the lips, nose, cheeks, and ears, presumably because of vascular stasis brought about by intravascular autoagglutination. Splenomegaly is moderate and is found in about two thirds of all of these patients; there may also be mild to moderate hepatomegaly, especially in the more severe cases. If the autoimmune hemolytic disease is secondary, physical findings include those associated with the underlying disease.

## Laboratory Findings

### Blood

The hematocrit and hemoglobin values vary, depending on the severity of the hemolytic process. The MCV is usually in the macrocytic range, reflecting a young population of cells. The absolute reticulocyte count is correspondingly high and may reach well over  $1000 \times 10^9/l$ , but concurrent infection with marrow shutdown or infiltration of the marrow by malignant cells may markedly reduce the degree of reticulocytosis. The blood will show regenerative macrocytosis, with considerable polychromatophilia and anisocytosis, often with a striking number of

microspherocytes. Occasionally, thin projections from the surface of red cells are seen. Nucleated red cells including macronormoblasts are frequently observed. Autoagglutination is a more characteristic feature of "complete" antibodies (page 924) but is seen with "incomplete" antibodies, particularly when the erythrocytes are strongly sensitized. When present, autoagglutination must be distinguished from rouleaux formation (page 1611). The white cell count may vary from that of a moderate leukopenia to that of a moderate leukocytosis; the platelet count usually gives normal values. Occasionally thrombocytopenia is noted and in some instances it is thought to be due to anti-platelet antibodies (see Evans' syndrome, page 1095).

The serum bilirubin level is moderately increased (usually 2.5 to 5 mg/dl) with a predominance of indirect-reacting pigment. When hemolysis is severe haptoglobin levels may be low or absent in spite of the predominantly extravascular destruction of the red cells; the plasma hemoglobin value usually is slightly elevated. Occasionally, massive hemoglobinemia, hemoglobinuria, and hemosiderinuria are seen, usually in patients with acute fulminant disease. In these subjects, methemalbumin may also be demonstrable spectroscopically. Mild forms of hemosiderinuria are not unusual in patients with chronic hemolysis and may indeed lead to iron-deficiency anemia.<sup>245</sup> Urine and fecal urobilinogen levels are correspondingly elevated and the latter may reach levels of over 1000 mg/day. The osmotic fragility usually is increased<sup>217</sup> in direct proportion to the number of spherocytes seen on the peripheral smear.

### Serologic Findings

When a positive reaction to the direct anti-globulin test is obtained in patients with hemolytic anemia, this constitutes strong evidence for an autoimmune or isoimmune etiology. Only rarely does a positive reaction occur in healthy persons<sup>295</sup> or in patients with nonimmune hemolytic anemias.<sup>217</sup> It is useful to determine the specificity of the serologic reaction. Initially, antiglobulin tests were

carried out with antisera prepared by immunizing animals with whole human serum. Naturally these reagents detected the presence of all gamma globulin classes, complement, and many other serum proteins. Most laboratories now use antisera that specifically react with IgG, complement, or one of the other immunoglobulin classes. In one representative study<sup>219</sup> of 43 patients with idiopathic or secondary autoimmune hemolytic anemia, 21 were found to react with anti-IgG only, 12 reacted with anti-IgG and anti-complement sera, and 7 reacted with anti-complement reagents only. A small number of patients ( $\frac{3}{43}$ ) also reacted with anti-IgA or anti-IgM sera. Positive reactions to complement specific Coombs' tests are particularly common in patients with systemic lupus erythematosus.<sup>267</sup>

Autoantibodies usually can also be demonstrated in the patient's serum when the reaction to the direct Coombs' test is positive and the patient is actively hemolyzing.<sup>219</sup> Methods using enzyme-treated cells are more sensitive and often reveal antibodies that cannot be demonstrated otherwise.<sup>217</sup>

ACQUIRED HEMOLYTIC ANEMIA WITHOUT DETECTED ANTIBODY. Occasionally, patients are encountered who have all the clinical manifestations of AIHA but in whom anti-red cell antibodies cannot be demonstrated by routine techniques.<sup>217</sup> Such patients may nevertheless destroy large volumes of transfused normal blood at rapid rates approximating the destruction of their own cells.<sup>233</sup> In some of these patients, plasma factors that promote the phagocytosis of red cells are found.<sup>275</sup> In others, it is possible to detect the presence of small quantities of anti-red cell antibodies by the more sensitive "complement-fixing antibody consumption technique,"<sup>249</sup> in which the patient's red cells and normal red cells are compared for their capacity to absorb anti-IgG from aliquots of specific rabbit antiserum. The reduction in anti-IgG antibodies is quantitated by a complement fixation test and the number of IgG molecules per red cell can then be derived from a standard curve. The number of IgG

molecules per sensitized red cell so detected is small (70 to 434 molecules per cell), but the serologic behavior of these antibodies appears to be similar to that of the traditional IgG antibodies of AIHA.<sup>210</sup> Why such small amounts of antibody should lead to overt hemolytic anemia is not clear, especially when one contrasts these patients with "Coombs'-positive normal people"<sup>295</sup> and with certain patients with strongly positive reactions to direct antiglobulin tests who only display the mildest hemolytic state.

With sensitive techniques it can be shown that the antibodies of about 70% of all patients with AIHA have specificity for some part of the Rh substance.<sup>296</sup> With rare exceptions<sup>213</sup> these antibodies will not react with Rh-null cells, which lack all antigenic components of the Rh complex (see Chapter 11); this suggests that the reacting antigen is some basic structural feature of the Rh complex. Most but not all<sup>208, 256</sup> of these antibodies are "less specific" than the isoantibodies developing after immunization with Rh antigens during pregnancy or transfusion<sup>219</sup>; on the other hand, this may simply be a reflection of the multispecificity of the antibodies in autoimmune hemolytic anemia.

When gamma globulins are eluted from sensitized red cells and their heavy chains are examined, they are found to be structurally heterogeneous.<sup>201, 268</sup> Occasionally, however, only one type of light chain is encountered and, when present, it is usually kappa.

## Treatment

When the diagnosis of AIHA is first made it is important to search for possible associated disorders such as tumors, lymphomas, and collagen vascular diseases (Table 27-5), since their therapy may take precedence over treatment of the hemolytic process as such. Indeed, effective therapy of the patient with a tumor or lymphoma may be accompanied by a remission of the hemolytic disease. Often, however, it is necessary to treat the hemolytic anemia as a separate entity by measures outlined below.<sup>253</sup>

*Blood transfusion* may be necessary as an

emergency measure, especially in patients with severe and fulminant disease, but its usefulness depends on the availability of more specific therapy, since the transfused blood is usually destroyed as rapidly as the blood of the patient. Occasionally, when the antibody has specificity for a well-defined red cell antigen, it may be possible to select blood lacking that particular determinant.<sup>298</sup> Usually, however, the specific antibody is accompanied by other "nonspecific" ones. In addition, it is frequently impossible to select blood not containing the specific antigen without also deliberately sensitizing the patient to other red cell antigens.<sup>298</sup>

*Blood typing and matching* may present special problems in AIHA. The patient's own erythrocytes may be difficult to type because of "blocking" of antigenic sites by antibody.<sup>217</sup> Under these circumstances it is sometimes possible to elute the offending antibody by heating the red cells to 56° C for 10 minutes.<sup>217</sup> More commonly, "nonspecific" antibodies found in the patient's serum make proper matching impossible because they appear to react with all donor cells in the indirect antiglobulin test. In such cases, it frequently is necessary to test as many donor samples as possible, and to select those whose red cells seem to give the best match. Such blood should only be used when absolutely necessary and must be administered very slowly and under constant supervision. Sometimes the use of such poorly matched blood is made relatively safe by the concomitant use of steroids (see below).

*The adrenocorticosteroid hormones* now constitute the initial therapy of choice in most patients with AIHA of the "incomplete" warm antibody type. Appropriate doses are those that achieve the desired clinical result; 40 mg/m<sup>2</sup> of body surface per day is a reasonable initial dose, but twice this amount or more may occasionally be needed. While the response to therapy is sometimes dramatic, hematologic improvement may not become evident before the third or fourth day, but it should always be evident within a week. There may be a transient increase in reticulocytes, and a weekly increment of 2 or

3 g of hemoglobin/dl of blood should occur. When the hemoglobin level has reached 10 g/dl or more, the therapeutic dose may be decreased gradually, the rate and degree depending on the hematologic response. After two or three weeks the indirect Coombs' reaction may become negative, but many patients undergo a remission with no demonstrable serologic change.

It is difficult to cite entirely satisfactory statistics for the effectiveness of adrenocorticoids in the treatment of patients with AIHA due to warm reactive, incomplete antibodies. It has been stated that complete relief from anemia can be expected in 70 to 90% of subjects,<sup>200,225,226</sup> with poorer results in those having the symptomatic forms. In perhaps a third of the patients with the idiopathic variety the remission will be sustained on complete withdrawal of therapy. In others, maintenance therapy in amounts of 5 to 20 mg prednisone per day may be required for many months and even years. Whatever may be the nature of the underlying cause in the patient achieving complete remission, it is likely that steroid therapy has simply made it possible for that patient to survive until spontaneous recovery has taken place. The ill effects of long-term treatment with steroids must always be borne in mind; these include increased susceptibility to infection, peptic ulceration, steroid myopathy, osteoporosis, hypertension, and diabetes. When large doses are used, salt restriction and the administration of potassium salts will usually be required. Insofar as possible, adrenocorticoid therapy should be held to the minimum dose compatible with satisfactory control of the hemolysis.

Steroids may ameliorate hemolysis in several ways. The earliest effect is probably due to the ability of these drugs to reduce the phagocytosis of antibody-sensitized cells by the RES, particularly the spleen.<sup>272</sup> In addition, there may be a rapid decrease in the concentration of cell-bound antibody, especially at high doses of steroids,<sup>282</sup> and this may further decrease the phagocytosis of red cells. Since the reduction of red cell antibody is accompanied by a rise in serum antibody,

the affinity of antigen for antibody has probably been altered by steroids.<sup>282</sup> Finally, in patients achieving remission, the concentration of serum antibody may fall to low levels<sup>282</sup> because of the known immunosuppressive properties of steroids.<sup>276</sup>

*Splenectomy* is recommended for patients whose anemia cannot be controlled by steroids during the acute phase of the disease, for those whose anemia requires continuous high-dose steroid therapy, or for those who have developed serious complications on relatively low doses of adrenocorticoids.<sup>219</sup> The results of splenectomy are improved greatly by selecting those patients who have demonstrated excessive sequestration of <sup>51</sup>Cr-labeled red cells within the spleen.<sup>213a,241</sup> Excessive sequestration is determined by withdrawing 25 to 50 ml venous blood and mixing this with ACD solution and 50 to 150 mc of <sup>51</sup>Cr. The mixture is incubated at room temperature for 30 to 60 minutes as in the procedure for measuring erythrocyte life span with <sup>51</sup>Cr-labeled red cells (page 197). Following re-injection of the tagged erythrocytes the anterolateral projection of the spleen is monitored with a unidirectional scintillation counter.<sup>259</sup> After equilibration over the spleen has been attained the anterior projections of the liver and the heart as well as of the spleen are counted. The relative uptakes of radioactivity over these organs are expressed in terms of splenic-precordial (S/P) and spleen-liver (S/L) ratios. Counting can be repeated daily or twice a week until a definite trend in the ratio becomes evident. A *splenic localization index (SLI)* has been devised as follows:

$$\frac{S/P}{S/P_0} \times 10 = \frac{d_{\max}}{d_{\max}} = SLI,$$

where S/P is the maximum change in the ratio,  $S/P_0$  is the initial ratio, and  $d_{\max}$  is the day on which the maximum ratio is found. Some workers have simply compared the ratio of radioactivity over the spleen with that of the liver.<sup>284</sup>

A maximum S/P ratio of 1.5 or more, an

S/L ratio of at least 2.0, and an SLI of 1.0 or higher indicate splenic sequestration and have been claimed to correlate well with other information regarding the major site of increased blood destruction. It is generally thought that patients manifesting marked splenic and little hepatic sequestration respond well to splenectomy.<sup>200,213a,211,292</sup> However, this view needs additional documentation since discrepancies do occur. In considering the desirability of splenectomy in AIHA subjects, it is therefore wise to give heed to clinical experience showing that patients with warm antibodies are more likely to respond than those with cold antibodies, that patients with splenomegaly respond better than those without a palpable spleen, and that those with incomplete antibodies, especially if present in relatively small amounts, are more likely to respond favorably to splenectomy than those with complete agglutinins or complement-fixing antibodies.

Before the introduction of steroid therapy it was reported that splenectomy was helpful in 50% of patients with AIHA,<sup>297</sup> but the duration of such remissions is not known. Even when steroids have been combined with splenectomy, high mortality rates have been cited.<sup>218</sup> Our own experience has not been as discouraging, although splenectomy should never be undertaken lightly; even in the best hands the mortality rate of the operation is considerable.<sup>217</sup> Atelectasis, subdiaphragmatic infections, and thromboembolic disease are the more common fatal complications. In addition, infants and children are particularly prone to develop pyogenic infections that carry high mortality rates (47%<sup>232</sup>), even when there is no other underlying disease.

Many cytotoxic drugs are known to be potentially immunosuppressive<sup>276</sup> and this property provides the theoretical basis for their use in AIHA. It is likely, however, that their therapeutic effect does not depend on immunosuppression alone, since clinical success need not be accompanied by a reduction in the titer of anti-red cell antibodies.<sup>248,287</sup>

Several drugs, including azathioprine,<sup>200,214,248</sup> 6-mercaptopurine,<sup>287</sup> thioguanine,<sup>287</sup> and cyclophosphamide,<sup>283</sup> have

enjoyed moderate success. Cyclophosphamide appears to be one of the most effective immunosuppressive agents available<sup>288</sup> and may have a better therapeutic index than do the other drugs.<sup>283</sup> None has been subjected to controlled trial.

As with steroid therapy, treatment is not without risk; serious infection may develop because general immunosuppression complicated by leukopenia and thrombocytopenia may occur. In addition, one needs to consider the increased incidence of tumors that accompanies long-term use of immunosuppressive agents,<sup>295,231</sup> as well as specific complications associated with some of these drugs, including bladder fibrosis with cyclophosphamide,<sup>252</sup> and their effect on the reproductive system.<sup>238,253,264,279</sup> In general, splenectomy is preferable to the use of cytotoxic drugs, but the latter may be useful if splenectomy fails and in patients unfit for a surgical procedure.

Although heparin has been useful in the management of some patients with AIHA,<sup>217,230,247,290</sup> its value as a practical measure of therapy remains uncertain.<sup>206,219</sup> The risk of hemorrhage and the difficulties of administration constitute serious disadvantages.

## Drug-Induced Immuno-hemolytic Anemias

Drug-induced immuno-hemolytic anemias are examples of diseases in which exposure to foreign antigens causes destruction of the sensitized individual's own cells. Although the number of recorded cases is relatively small, these anemias hold an unusual interest because they provide some insight into the nature of "autoimmune" phenomena in general. Furthermore, many cases of AIHA now considered to be "idiopathic" may eventually prove to be drug induced, especially when one considers that some drugs<sup>310</sup> seem to induce the production of antibodies against well-defined red cell antigens but have no recognizable cross reactivity with the trigger agent.

Drugs can lead to the destruction of red cells by several different immune mechanisms which have been named after the drug that best characterizes each group. These mechanisms are illustrated in Table 27-6. Currently recognized are those typified by (1) stibophen, (2) penicillin, and (3)  $\alpha$ -methyldopa; other drugs that act similarly are listed in Table 27-7.

### Drug-Induced Immuno-hemolytic Anemia of the Stibophen (or "Innocent Bystander") Type

#### Pathogenesis

Drug-induced hemolytic anemia of the "innocent bystander" type was first described by Harris (1954) in a patient being treated with stibophen because of schistosomiasis.<sup>330</sup> It was shown that the patient's serum contained a factor that could sensitize his own or foreign red cells to become Coombs' positive; that sensitization could lead to agglutination of normal cells and to complement-dependent lysis of trypsinized red cells or cells from a patient with paroxysmal nocturnal hemoglobinuria; and that all of these reactions, including the hemolytic reaction *in vivo*, depended on the presence of the drug.

It was subsequently shown that the deposition of anti-drug antibodies on cell surfaces involved two separate but interdependent reactions.<sup>353</sup> First, anti-drug antibodies react specifically with a stable complex of the drug and some soluble noncellular macromolecule

to produce a relatively large antigen-antibody aggregate. In the second reaction the antigen-antibody complex is thought to settle out on various cell surfaces, such as red cells, platelets, or other tissues. This step is immunologically nonspecific since it does not involve specific interactions between red cell antigens and the antigen-binding sites of the anti-drug antibodies. Nevertheless, for reasons that are not yet clear, the adsorption of antigen-antibody complexes to cells seems to proceed as avidly as the interaction between drug and anti-drug antibody in the immunologically specific first step.<sup>353</sup> The anti-drug antibodies may be IgG, IgM, or both and usually have the ability to bind complement, which is ultimately responsible for the cell lysis.

Intravascular destruction of red cells by complement-dependent mechanisms proceeds very rapidly (see page 892), and red cell sensitization by antigen-antibody-complement complexes may therefore escape detection if Coombs' test is carried out with anti-gamma globulin sera only. If Coombs' test is performed with anti-complement or "non-gamma globulin" sera, however, its reaction characteristically is positive in patients with the stibophen type of hemolytic anemia, and may remain so for up to two months after the initial insult. This is due to the persistence of sublytic amounts of complement on many red cells that, for unknown reasons, have shed their drug-antibody complexes. Attachment of the complement components appears to be virtually irreversible and, when present in sublytic quantities, complement

Table 27-6. Reactions in Three Types of Drug-Induced Hemolytic Anemias

Type of Reaction	Role of Drug or Drug Metabolite	Nature of Attachment of Antibody to RBC	Antiglobulin Reaction	Mechanism of Cell Destruction
Hapten (penicillin)	Cell bound hapten	To cell bound drug	Ig	Agglutination
Innocent bystander ("stibophen")	Antigen in circulating antigen-antibody complex	Adsorption as part of antigen-antibody-complement complex	C	Complement lysis
"Alpha-methyldopa"	Triggers formation of anti red cell antibody. No cross reactivity with drug	To Rh site on RBC membrane	Ig	Agglutination

components may constitute the only evidence of antecedent immune complex activity. Similar reactions have been documented for a number of other drugs that are listed in Table 27-7.

It is not at all certain how drug-specific antibodies are generated. Since all of these drugs are of low molecular weight, they undoubtedly behave as true haptens and are therefore incapable of eliciting an immune response unless they are first bound firmly to a carrier protein that must itself be immunogenic. Autologous proteins would therefore only qualify as carriers if they were sufficiently distorted by haptenic conjugation or some other process to make them appear "foreign." The mechanisms by which this might occur are not clear.

### Clinical Manifestations

The dose of the offending drug is usually small and hemolysis only occurs in the presence of the medication. In most patients the picture is one of acute intravascular hemolysis with hemoglobinemia and hemoglobinuria. There is a high incidence of renal failure<sup>359</sup> and disseminated intravascular co-

agulation has been described.<sup>356</sup> The laboratory findings are those characteristic of intravascular hemolysis (page 728). Occasionally this is accompanied by leukopenia and/or thrombocytopenia. Spherocytosis may be evident on the blood smear. The serologic characteristics of the hemolytic antibodies have been described previously. Occasionally the antibodies may have agglutinating properties only, especially those with specificity for para-aminosalicylic acid.<sup>350</sup>

### Treatment

It is imperative that use of the offending drug be discontinued immediately. In some patients with a mild hemolytic process no additional treatment may be necessary. When hemolysis has been extensive and the hemoglobin level is low, blood transfusions are required; however, these may be of limited benefit since the transfused cells may be destroyed as rapidly as the patient's own erythrocytes. If drug-antibody complexes are still circulating in the patient's serum, some difficulty may also be encountered in cross-matching.

Since the hemolytic process is mainly of the intravascular variety, steroids are unlikely to be of benefit. Renal failure becomes a problem in about half the patients with intravascular hemolysis of this type.<sup>359</sup> Proper management of this complication is critical and has been discussed in detail in Chapter 11.

### Drug-Induced Hemolytic Anemia of the Penicillin Type

#### Pathogenesis

The mechanisms responsible for penicillin-induced hemolytic anemia differ significantly from those responsible for the stibophen type of hemolytic anemia. While the offending antibody in both instances has specificity for the drug and not some component of the erythrocyte membrane, anti-penicillin antibodies can only bind to red cells if the drug is first firmly coupled to the

erythrocyte membrane, probably by covalent bonds.<sup>337</sup> This is to be distinguished from the stibophen type of hemolytic anemia, in which circulating antigen-antibody complexes settle out on red cells and then lead to complement-dependent lysis of their innocent host (above). Some degradation products of benzylpenicillin are able to bond covalently to proteins<sup>335,336,337</sup>; of these the benzylpenicilloyl group appears to be the "major" haptenic determinant of benzylpenicillin hypersensitivity, accounting for at least 95% of all benzylpenicillin derivatives reacting irreversibly with protein.<sup>335</sup> In addition, several "minor" determinants are formed. Although called "minor" because they occur in comparatively smaller amounts, they nevertheless have a great deal of clinical significance.<sup>335</sup> Both major and minor determinants, separately or in combination, may be involved in red cell sensitization by penicillin.<sup>337,349</sup>

Sensitization to penicillin occurs only when relatively large doses, perhaps of the order of 20,000,000 units per day or more, are used.<sup>337,359</sup> It is, however, noteworthy that high-dose intravenous penicillin therapy, though necessary for coupling of penicillin to red cells, does not usually result in a high-titered anti-penicilloyl antibody response.<sup>338</sup> The latter depends on the administration of intramuscular penicillin, given either before or after intravenous therapy.<sup>337</sup> Thus, both high-dose penicillin therapy and antibodies of high titer or great affinity are needed to produce Coombs' positivity or hemolysis. The anti-penicillin antibodies are usually IgG, warm reactive, and noncomplement binding, but exceptional cases of hemolytic anemia due to complement-mediated mechanisms have been described.<sup>332</sup>

### Clinical Manifestations

As mentioned previously, patients with penicillin-induced hemolytic anemia have almost always received large doses of the drug, usually over a protracted period. The hemolytic process may be brisk with a rapidly falling hemoglobin level, reticulocytosis, and indirect hyperbilirubinemia, but without

clinical evidence of intravascular hemolysis. <sup>51</sup>Cr-tagged red cells are rapidly removed from the circulation and there is marked accumulation of radioactivity over the spleen.<sup>348</sup> Red cell destruction probably occurs mainly within the spleen. Spherocytosis is only rarely present<sup>359</sup> and the blood shows no other diagnostic features. At the time of hemolysis, all patients give a strongly positive reaction, of the anti-gamma globulin type, to the direct Coombs' test. If the sensitizing antibody is eluted it is found to have specificity for penicillin derivatives only and not for antigenic determinants of the red cell membrane. If penicillin therapy is stopped, the hemolysis ceases quickly and the reaction to the direct Coombs' test gradually becomes weaker over a period of days or weeks.

### Treatment

If the patient is actively hemolyzing, penicillin therapy should be discontinued immediately and structurally related congeners should not be substituted. Blood transfusions may become necessary; transfused cells should survive well if penicillin therapy has been discontinued and most of the drug has been excreted. Since red cell destruction in penicillin-induced immuno-hemolytic anemia is mainly extravascular and presumably splenic,<sup>348</sup> steroids should be of benefit, although protracted hemolysis has been described in the face of steroid therapy.<sup>319</sup>

### Drug-Induced Hemolytic Anemia of the Alpha-Methyldopa Type

Alpha-methyldopa is a widely used anti-hypertensive drug that is known to be a potent inhibitor of dopa decarboxylase, both *in vivo* and *in vitro*. In 1966 it was first reported that a high proportion of patients receiving this drug gave a positive reaction to the direct antiglobulin test and that a few of them developed an overt hemolytic anemia serologically identical with idiopathic autoimmune hemolytic anemia.<sup>358</sup> These observations were subsequently confirmed.

## Pathogenesis

Although the mechanism by which alpha-methyldopa leads to antierythrocyte antibody production is unknown, several observations are of extreme interest. The autoantibody is only formed after prolonged therapy and this time interval is not shortened with reexposure.<sup>358</sup> When use of the drug is stopped, the antibody titer declines and the reaction to the Coombs' test becomes negative in a few weeks or months, depending on the strength of the original reaction.<sup>358</sup> Only occasionally does the antiglobulin reaction remain positive for as long as two years.<sup>359</sup> The antibodies readily sensitize normal red cells in the absence of the drug, and the reaction cannot be inhibited by pre-incubation of antisera with alpha-methyldopa or several of its metabolites or congeners.<sup>310</sup> This suggests that there is no cross-reactivity between the drug and the red cell antigen with which the antibody interacts. It is of particular interest that the anti-red cell antibodies developing during alpha-methyldopa therapy have specificity for Rh antigens and that the pattern of specificity is similar to that described in idiopathic autoimmune hemolytic anemia. Thus, while some antibodies appear to react preferentially with well-defined Rh antigen such as hr(c) or hr''(e), others react with antigenic determinants common to all erythrocytes except those of the Rh-null type, which lack all antigenic determinants of the Rh complex.<sup>320</sup> Alpha-methyldopa-induced anti-red cell antibodies may therefore have specificity for some basic and commonly shared structural component of the Rh substance. The Coombs' reaction is positive with anti-gamma globulin sera and eluted antibodies have shown considerable structural heterogeneity,<sup>320</sup> suggesting a polyclonal pattern of immune responsiveness. In addition to anti-red cell antibodies, other autoantibodies are demonstrable in a large number of patients receiving alpha-methyldopa. These include antinuclear factors, rheumatoid factor, and antibodies against gastric mucosa.<sup>358</sup> Thus anti-red cell antibodies constitute only one of a number of non-cross-reacting autoimmune

responses induced by alpha-methyldopa, making it even more unlikely that the antibodies have specificity for some congener or degradation product of the drug and simply cross-react with normal tissue components.

There is no good explanation for the induction of autoantibodies by alpha-methyldopa therapy. The obvious hypotheses have been summarized by Worledge,<sup>358</sup> but none of these seems entirely satisfactory. The importance of elucidating the alpha-methyldopa mechanism cannot be underestimated, however, since it illustrates the induction of an autoimmune process by an extrinsic agent that does not itself appear to participate in the immune process that it has generated. It follows that extrinsic causative agents, and particularly drugs and viruses, must be suspected in all cases of so-called AIHA. Indeed so-called AIHA of the alpha-methyldopa type has already been described in association with another drug, mefenamic acid.<sup>331</sup>

## Clinical Manifestations

Alpha-methyldopa produces a positive reaction to Coombs' test in about 15% of all patients who have received the drug for a period of three months or more,<sup>359</sup> but most of these patients are not anemic and show no evidence of increased hemolysis. The incidence of hemolytic disease has ranged from none to even as high as 5% of all patients taking the drug; an overall incidence of 0.6% was noted by Worledge in a summary covering 14 separate studies and nearly 1400 patients.<sup>339</sup> In spite of this low incidence the total number of autoimmune hemolytic anemias due to alpha-methyldopa exceeds the total number of all other drug-induced immuno-hemolytic anemias described so far.

The onset of hemolysis has ranged from 18 weeks to four years after the start of therapy.<sup>359</sup> It is invariably insidious and the course of the disease is slowly progressive. No specific clinical features have been described. The symptoms are primarily those of anemia. The hematologic features are identical to those described for AIHA due to incomplete warm reactive autoantibodies

(above) with evidence of accelerated red cell production and mild to moderate spherocytosis, a proportionately variable increase in reticulocytes, and mild to moderate indirect hyperbilirubinemia. Reaction to the Coombs' test is positive with anti-gamma G sera only. Occasionally, reactions to tests for antinuclear antibodies and rheumatoid factors also may be positive.<sup>358</sup>

### Treatment

Most patients with hemolytic disease due to alpha-methyldopa require no therapy other than withdrawal of the offending drug.<sup>339</sup> Often recovery is surprisingly quick,<sup>327</sup> and in these patients the hemoglobin level may begin to rise as soon as use of the drug has been stopped. When hemolysis is more severe or does not readily come under control, steroid therapy is advisable and is usually effective.<sup>321,354</sup> Nevertheless, three deaths have been reported among 34 patients so treated.<sup>321,354</sup> This is an unusually high death rate from AIHA, undoubtedly attributable in part to the fact that alpha-methyldopa therapy is often given to patients who already are at high risk due to serious cardiovascular disease; the occurrence of hemolytic anemia in such patients should therefore never be treated lightly.

Blood transfusions may be necessary, as in patients with idiopathic autoimmune hemolytic anemia (above), and, as in patients with AIHA, difficulties in cross-matching may be encountered.

## Immunohemolytic Anemias Due to Cold Reactive Antibodies

Some antibodies react most efficiently with red cell antigens at temperatures below 32° C and are therefore called "cold reactive antibodies." Autoantibodies of this type may give rise to one of two clinical syndromes, depending on the functional properties of the anti-red cell antibodies involved (Table

27-5). The *cold agglutinin syndrome* is the more common of the two and accounts for about a third of all patients with autoimmune hemolytic anemias, whereas the syndrome of *paroxysmal cold hemoglobinuria* due to hemolysins is rare and is most characteristically found in association with congenital or acquired syphilis. The antibodies giving rise to these clinical syndromes belong to separate immunoglobulin classes, interact with different red cell antigens, and may give rise to distinct clinical manifestations. The two syndromes will therefore be discussed separately.

### Cold Hemagglutinin Disease

#### Etiology and Pathogenesis

Many theories have been proposed to explain the production of anti-red cell antibodies. These have been discussed in relation to immunohemolytic anemias due to warm reactive antibodies (page 910) and are equally applicable to the production of cold reactive antibodies. The latter occur most commonly in association with infectious or malignant diseases, but sometimes take place in the absence of known underlying causes. The infections that most commonly give rise to cold reactive antibodies are those due to *Mycoplasma pneumoniae*,<sup>323,414,415</sup> although a few cases have also been described in association with infectious mononucleosis.<sup>416,421</sup> Most cold reactive antibodies arising during these infections have specificity for the I-i antigens (Chapter 11) of red cells,<sup>414,416,439,443</sup> but a few antibodies that react equally well with all adult cells, cord blood cells, and adult i cells have also been described, suggesting that these have specificity for some other antigen (SP<sub>1</sub>) common to all human red cells.<sup>415,427</sup> Some observers have suggested that the anti-I specificity of cold agglutinins in *M. pneumoniae* infections is due to the sharing of I type antigenic determinants by *M. pneumoniae* and human red cells,<sup>253,396</sup> but this has been denied by others.<sup>233</sup> Additional support for the shared antigen theory comes from the observation that rabbits

immunized with *M. pneumoniae* also produce high titers of anti-I cold agglutinins.<sup>386,396</sup> Antibodies of similar specificity are produced by immunizing rabbits with *L. monocytogenes*<sup>395,396</sup> and streptococcus MG.<sup>396</sup>

Cold agglutinins found in patients with malignant disease may have either anti-I or anti-i specificity,<sup>321,385,425,450</sup> whereas sera of patients with the idiopathic cold hemagglutinin syndrome almost always have anti-I or, occasionally, anti-Sp<sub>1</sub> specificity.<sup>113,450</sup> These antibodies have no demonstrable cross-reactivity with *M. pneumoniae*.<sup>395</sup> Cold agglutinins found in some normal sera usually react with the I antigen.<sup>423</sup>

Almost all cold agglutinins are IgM, although rare cases of IgA cold agglutinins have been recorded.<sup>450</sup> IgM antibodies readily fix complement and can be shown to lyse red cells in vitro if the pH is adjusted to 6.5 to 7.0.<sup>397</sup> Dissociation of the 19S anti-I molecule into single 7S components results in loss of complement-fixing ability, without destroying the antibody's ability to cause agglutination.<sup>392</sup> Sometimes, and particularly in idiopathic cold agglutinin disease, the concentration of cold agglutinins may be so high as to give rise to abnormal peaks in electrophoretic patterns or to result in the formation of cryoprecipitates when the serum is immersed in ice.<sup>411</sup> In the idiopathic form of the syndrome the cold agglutinins appear to be of monoclonal origin, as judged by electrophoretic and structural studies.<sup>383,384,401,450</sup> They are considered to represent a special form of plasma cell dyscrasia<sup>443</sup> (Chapter 53). The post-infectious variants of the disease are polyclonal in origin, suggesting a reaction to an underlying infectious stimulus.<sup>414,443,450</sup>

Cold agglutinins usually do not react with red cells at temperatures of 32° C or higher. As the temperature is lowered towards 0° C the agglutinin titer quickly and progressively increases and complement fixation occurs; but while antibody binding and complement fixation are optimal at low temperatures, complement is most lytic at high temperatures (40° C). Thus hemolysis only occurs in the temperature range of 10 to 30° C where these two activities overlap, with maximal lysis at

about 22° C; at this temperature a sufficient amount of antibody remains fixed to the cell, and complement lytic activity, though not optimal, is of sufficient magnitude to result in hemolysis<sup>443</sup> (Fig. 27-4). Occasionally the base of the triangle may broaden to the right, indicating a higher thermal range of hemolytic activity and a more serious form of the disease.

Since normal serum contains an inactivator of membrane-bound C3 (C3bINA, see Chapter 7), hemolysis only occurs if complement fixation is sufficiently rapid to outdistance the effects of the inactivator.<sup>423,425</sup> This is ordinarily the case with acute cold stress. If hemolysis does not occur, antibody disengages itself from the cell at higher temperatures, while inactivated complement (C3) remains fixed. These inactivated complement components are responsible for the positive "non-gamma globulin" Coombs' reaction seen in cold agglutinin disease (page 924). Red cells that have once escaped hemolysis become unusually resistant to further complement lysis.<sup>391</sup>

While complement-mediated lysis accounts for most of the red cell destruction in the cold agglutinin syndrome,<sup>421</sup> other factors may play a role, including the striking

Fig 27-4. Schematic combination of the temperature ranges for cold agglutinin fixation and lytic complement action (From Schuboth, <sup>441</sup> courtesy of the author and *Seminars in Hematology*)

changes in red cell contour brought about by cold agglutinins. These are demonstrable by the electron microscope.<sup>440</sup> While the changes are reversible on warming, they impose considerable structural rigidity on cells trapped in cooled surface areas; indeed, agglutinated cells are known to be highly susceptible to mechanical trauma *in vitro*<sup>217</sup> and it is likely that a similar antibody-induced propensity to lysis exists *in vivo*.

### Clinical Manifestations

Chronic idiopathic cold agglutinin disease is predominantly a disease of the elderly, with a *clearcut peak incidence in the seventh and eighth decades of life*.<sup>217,443</sup> A few patients in their twenties and thirties are included in large series, however, and the disease is occasionally described in childhood.<sup>443</sup> The cold agglutinin syndrome seen in patients with malignant disease follows a similar age distribution, whereas that associated with viral pneumonia is most common during the third to fifth decades of life.<sup>217</sup>

The clinical manifestations are predominantly due to vascular disturbances or hemolysis and reflect the functional properties of the patient's cold agglutinins.<sup>441</sup> Thus patients with a high hemagglutinin and a high hemolysin titers suffer from vascular disturbances as well as hemolysis. A smaller group of patients have a high agglutinin titer but hemolytic activity may only be demonstrable by the use of trypsinized red cells, and such patients have vascular disturbances in the cold but no hemolytic disease. In a very occasional patient, intravascular hemolysis constitutes the predominant clinical feature and in such an individual a relatively low cold agglutinin titer is associated with unusually intense hemolytic activity *in vitro*.

The circulatory changes are commonly described as "*acrocyanosis*" and are caused by the intracapillary agglutination of red cells in those areas of the body that are cooled to temperatures encompassed by the thermal range of the antibody in question. This results in a striking discoloration of the skin that may vary from a sick-looking white to deep blue-violet. The color changes may be

accompanied by numbness and occasionally by pain. Although the vascular disturbances are potentially reversible, signs of chronic tissue damage, including trophic changes of the extremities and even gangrene, may eventually supervene.<sup>397,400,430,433,445</sup> Acrocyanosis or "Raynaud's phenomenon" may involve any part of the body, but the exposed distal extremities, the tip of the nose, and the ear lobes are most commonly affected. Acrocyanosis may be precipitated by a useful diagnostic maneuver, the *ice cube test*, which produces a circumscribed area of intravascular agglutination and acrocyanosis in the hyperemic palm.<sup>443</sup> While acrocyanosis may be the result of red cell agglutination, tissue gangrene is often associated with the presence of cryoglobulins.<sup>397,400,433</sup> These may produce a localized form of the hyperviscosity syndrome (page 1625), thereby contributing to the production of acrocyanosis and irreversible tissue damage.

Patients suffering from the idiopathic cold agglutinin syndrome usually develop a *chronic hemolytic process* of moderate severity; it is rare for the hemoglobin concentration to drop below 7 g/dl.<sup>394</sup> In northern climates the anemia appears to be worse during the winter,<sup>217</sup> but patients with high titers of cold agglutinins usually have a chronic hemolytic process regardless of temperature. When an acute cold-induced episode of intravascular hemolysis and hemoglobinuria is superimposed on the chronic disease, it often is accompanied by fever, chills, or renal shutdown.

Hemolytic disease due to cold agglutinins rarely accompanies pulmonary infections due to *M. pneumoniae*,<sup>444</sup> but when it does the hemolysis is of more abrupt onset and may occasionally be severe. The process is self-limited, however; the cold agglutinin titer usually drops to normal levels within three to four weeks. Other secondary forms of the cold agglutinin syndrome, usually accompanying malignant disease of lymphoid origin, tend to be more chronic. Hemolytic disease is not usually a prominent feature of the clinical picture, which is most frequently dominated by the underlying illness.<sup>443</sup>

In the idiopathic variant there are no strik-

ing *physical findings* other than those related to acrocyanosis, anemia, and perhaps mild jaundice. The patient usually is in good general condition, the spleen is frequently just palpable at the costal margin, and the liver may be slightly enlarged. Patients with cold hemagglutinin disease associated with infection or a malignant condition will have signs of the underlying disorder.

The effect of cold on intravascular hemolysis may be demonstrated by the "Ehrlich finger test." After the venous return of a finger has been occluded with a rubber band, the digit is immersed in cold water (20° C) for 15 minutes. At the same time, to serve as a control, another digit is occluded but is immersed in warm water (37° C). The centrifuged capillary blood obtained from the finger that was immersed in cold water is usually markedly hemolyzed as compared to that of the control.

## Laboratory Findings

### Blood

The hemoglobin and hematocrit values reflect the degree of hemolysis and may show considerable variation in relation to seasonal and other factors. The reticulocyte count is correspondingly elevated. Red cell counts and blood smear preparations may be made with difficulty unless they are carried out on fresh, warm specimens and the equipment is prewarmed to prevent cold agglutination. This is particularly true when dealing with blood containing high titers of antibody, as an increased thermal range is usually found under these conditions. Often cold agglutination is first discovered in the counting chamber, and may be confirmed by demonstrating the dissolution of clumps upon warming. Aside from some degree of autoagglutination, the blood smear is not remarkable and simply reflects the regenerative effort of the marrow. Spherocytosis is usually not striking and nucleated red cells are seldom present in large numbers.

The serum bilirubin is rarely more than

3 mg/dl and is predominantly indirect reacting. There may be other signs of mild intravascular hemolysis such as hemoglobinemia, low or absent haptoglobin levels, and chronic low-grade hemoglobinuria and hemosiderinuria. The latter may become more conspicuous in cold weather.

The stool contains an increased amount of stercobilinogen.

### Serologic Findings

In the presence of significant hemolysis the cold agglutinin titer (assessed at 4° C) may range from  $\frac{1}{1000}$  to  $\frac{1}{1,000,000}$ , but titers of  $\frac{1}{20,000}$  are more usual. In patients with infections the titer generally is lower ( $< \frac{1}{4000}$ ) even in the presence of hemolysis.<sup>414</sup> As was pointed out above, the hemolytic activity of the serum correlates more closely with the hemolysin titer than with the hemagglutinin titer. When measuring agglutinin titers it must be remembered that the titer may rise 10,000- to 100,000-fold when the temperature is lowered from 30° C to 0° C, and that the process is readily reversible if the test system is allowed to rewarm. In addition, the titer is usually higher when normal red cells are used instead of the patient's own erythrocytes. This may be related to the prior binding of complement components to the patient's red cells.<sup>350,393,394</sup> Most cold agglutinins have anti-I specificity, but anti-i and anti-Sp<sub>1</sub> antibodies also occur. The structural properties of cold agglutinins were discussed earlier. Complement levels are usually decreased while hemolysis is in progress.<sup>350</sup>

The reaction to the direct Coombs' test is positive even if the erythrocytes are not cooled prior to testing. It is specific for complement components; anti-gamma globulin sera typically give no reactions. The previously described "incomplete cold antibodies" are artifacts occasioned by the use of nonspecific Coombs' sera; agglutination was, in fact, caused by the reaction of anti-complement antibodies contained in such sera with complement components fixed to the patient's red cells.<sup>217</sup>

## Therapy

### Primary Chronic Cold Agglutinin Disease

Many patients have a mild, chronic hemolytic process requiring no specific therapy. When exacerbations of moderate severity occur they often respond to simple measures such as warmth and bed rest. It is advisable to avoid giving *blood transfusions* since they may be associated with acceleration of the hemolytic process. Because this reaction has been attributed to the infusion of fresh complement components, the use of washed red cells has been recommended. However, it seems likely that the patient's own erythrocytes are protected by the prior binding of sublytic amounts of complement.<sup>390,393,394</sup> According to this theory the donor erythrocytes should be responsible for the accelerated hemolysis and this has indeed been documented.<sup>395</sup> There may also be problems in cross-matching, especially if the procedure is carried out at temperatures below 32° C.

*Splenectomy* and *steroids* are usually not effective in the therapy of chronic cold agglutinin disease<sup>443</sup> although occasionally success has been reported. However, such success probably is attributable to other concomitant care; bed rest is usually as effective as therapy with ACTH or cortisone.<sup>358</sup> The lack of success with splenectomy or steroids is not surprising when one considers the pathogenesis of cold hemolysis.

The most rational therapy of the cold agglutinin syndrome is aimed at the suppression of antibody production. This can usually be accomplished by the use of agents such as cyclophosphamide<sup>443</sup> or chlorambucil.<sup>219, 412,431</sup> Drastic reductions in titer and amelioration of the hemolytic process have been reported.

### Secondary Cold Agglutinin Disease

The treatment of *acute transient cold agglutinin disease accompanying viral pneumonia* presents fewer problems than does the primary chronic disease, since the disease is

self-limited and cold agglutinin titers usually return to harmless levels within two to three weeks. Usually no specific therapy is necessary. When the cold agglutinin syndrome accompanies *malignant disease*, therapy must be aimed at the underlying disorder.

## Paroxysmal Cold Hemoglobinuria

Paroxysmal cold hemoglobinuria (PCH) is characterized by the sudden passage of hemoglobin in the urine following local or general exposure to cold. Since this is such a dramatic occurrence, PCH was the first of all hemolytic anemias to be recognized and described.<sup>217</sup> The clinical features were well defined by the end of the 19th century, including the effect of cold exposure,<sup>390,405,406</sup> the derivation of the urinary pigment from circulating red cells,<sup>392,419,434</sup> and the etiologic relationship to syphilis.<sup>401</sup> In 1904, Donath and Landsteiner<sup>391</sup> published their classical paper outlining the basic pathogenetic mechanisms of the disease. They showed that the hemolysis was most likely due to an "autolysin" that unites with the patient's erythrocytes at low temperatures, and that labile serum factors cause lysis of the sensitized cells if the temperature is subsequently raised.

## Etiology and Pathogenesis

The Donath and Landsteiner (D-L) antibody has since been identified as a 7S IgG antibody that is a remarkably powerful hemolysin, even in relatively low concentrations. It has frequently been referred to as "biphasic" because chilling to 0° C, followed by warming to body temperature, as in the classic D-L test, leads to the most efficient lysis. The requirement for prior cooling depends on the fact that D-L antibodies bind to red cells most avidly at temperatures of less than 15° C, which are too low for lysis by complement. Nevertheless, antibodies of greater thermal range are sometimes encountered; these will lead to "monophasic" lysis if the cell-serum suspension is simply allowed to stand at 15 to 25° C.

Maximum hemolysis is only seen if complement also is present at the time of antibody binding in the cold phase, perhaps because complement facilitates the fixation of antibody to the cell<sup>217</sup> or because it retards the rate of its elution on subsequent rewarming.<sup>410</sup> Hinz and coworkers showed that D-L antibodies from several patients caused no more than a trace of lysis if complement had been omitted in the cold phase.<sup>408,410</sup> The complement component required during the cold phase has been identified as IIS Clq<sup>409</sup> (Chapter 7). This fixes to the cell surface in the presence of antibody and is followed by fixation of the C1r and C1s components in the presence of calcium ions; during the warm phase C4, C2, magnesium, and C3,5,6,7,8 and 9 in sequence are necessary for lysis.<sup>410,411</sup>

Since the D-L antibody is an IgG immunoglobulin, red cells sensitized with it will give a positive reaction to Coombs' test with an anti- $\gamma$ G serum, if the test is carried out in the cold. If sensitized cells are first washed at 37° C, the anti-gamma globulin serum will not bring about agglutination, although a broad-spectrum serum or an anti-complement Coombs' serum will agglutinate these cells at any temperature, provided the original sensitization to the D-L antibody occurred in the presence of complement.

Although the D-L antibody usually is thought of as a hemolysin, it is likely that the antibody regularly causes some agglutination as well as lysis, especially if the former is looked for in the absence of complement.<sup>217,418,422</sup> Unlike cold agglutinins which have anti-Ii specificity, cold hemolysins of the D-L type have specificity for the Pp blood group system<sup>422</sup> (Chapter 11). Although the antibody specificity initially seemed to be identical to that of the anti-Tja isoantibody found in the serum of pp subjects, more recent work has established that p<sup>k</sup> cells as well as pp cells are unaffected by the D-L antibody. Its specificity is therefore more correctly referred to as anti-P.<sup>421</sup> The specificity of the antibody seems to be the same in syphilitic and non-syphilitic patients.

The antibody is classically described in patients with tertiary syphilis or congenital

syphilis, but it is also seen in the absence of either disease. Thus of eleven patients studied by Worledge and Rousso<sup>421</sup> only three were definitely syphilitic and five were definitely non-syphilitic. Of the latter group, the manifestations in one followed measles and in another it followed mumps infection. Other investigators have also demonstrated the presence of the D-L antibody for short periods following viral infections, especially measles and mumps.<sup>217,381,411,445</sup>

The reason for the development of the D-L hemolysin in any of these situations is not known. Although a third of all patients with this antibody have a positive Wassermann reaction, the D-L hemolysin has been shown to be distinct from the antibodies that give rise to the positive reactions to the various biologic tests for syphilis.<sup>408</sup> It may be present transiently or for prolonged periods and does not always disappear with antiluetic therapy. Since PCH is rare but has been described in more than one family member,<sup>217</sup> it is likely that genetic factors controlling immune responsiveness<sup>260</sup> play a role in determining who develops the D-L autoantibody.

### Clinical Manifestations

The most striking manifestation of PCH is the passage of dark-brown or black urine after local or general exposure to cold. In some patients the disease is precipitated by brief exposure to moderate cold, whereas, in others, prolonged exposure to severely chilling temperatures is required. Systemic symptoms appear any time from a few minutes to eight hours after chilling and may consist of aching and pain in the back, legs, or abdomen; cramps; general malaise; headache; vomiting; diarrhea; and, finally, severe shaking chills and fever. The hemoglobin-containing urine is passed during the attack or shortly thereafter, but gross discoloration may only be evident in the first two or three specimens. Following the acute attack the patient is weak, pale, and may be slightly icteric. The spleen often is somewhat enlarged, and the liver may be palpable. Vasomotor disturbances such as urticarial

wheals, unusual sensitivity to frostbite, and acrocyanosis have been described.<sup>217</sup>

Sometimes the symptoms are milder; hemoglobinemia may occur without hemoglobinuria and only moderate fever and icterus may develop. Recovery from the attack usually is rapid and between attacks the patient may be entirely symptom free.

## Laboratory Findings

### Blood

Hematologic findings are those typical of acute intravascular hemolysis (page 728) and the severity of the changes reflects the severity of the attack. During sudden massive hemolytic episodes the hemoglobin level may drop rapidly, the plasma becomes markedly red, and, once the haptoglobin has been saturated, hemoglobinuria occurs. At this time, methalbumin also becomes detectable in the plasma and a mild to moderate elevation of unconjugated bilirubin follows. No diagnostic changes in the morphologic appearance of the red cells are seen, but erythrophagocytosis is a common feature of acute attacks. Leukopenia develops early and this is later followed by granulocytic leukocytosis; a considerable number of immature leukocytes may be present in the blood smear. In persons subjected to continuous cold weather and repeated attacks, chronic hemolytic anemia with hemosiderinuria may develop.

### Urine

The urine contains hemoglobin and methemoglobin, giving it a dark-red, brown, or almost black appearance. Occasionally red cell casts or ghosts are found in the urinary sediment, and albuminuria has been described. As already stated, the urinary abnormality may be confined to the first two or three specimens obtained after an attack.

### Serologic Findings

The reaction to the direct Coombs' test is positive during the attack and shortly thereafter if a complement-specific ("non-gamma

globulin") antiserum is used. The positive reaction is due to those cells that are coated by inactivated complement components or sublytic quantities of the active forms. Antibodies can usually not be demonstrated on red cells, since these dissociate on warming. The reaction to the indirect Coombs' test may, however, be positive if the test is performed in the cold, and, as pointed out earlier, normal erythrocytes give better reactions than do the patient's own cells.

In addition to the Ehrlich finger test, described earlier (page 924), a number of other tests are available for demonstrating antibodies in vivo and in vitro.

In the *Rosenbach test*, an attack of hemoglobinemia and hemoglobinuria may be produced by immersing the patient's hands or feet in ice water for 10 to 20 minutes. Occasionally, all four extremities must be immersed in order to produce a positive reaction. Since serious symptoms may arise in sensitive patients this test is not recommended for general use and should certainly not be attempted unless it is known that less exposure, as in the Ehrlich test, will not produce hemoglobinemia.

In the *Donath-Landsteiner test*, hemolysis is demonstrated following chilling of the blood in vitro. A rough test (MacKenzie)<sup>124</sup> is carried out as follows: Two or 3 ml of blood are taken from the patient and the same amount from a normal individual. Each sample is placed in a separate test tube and allowed to clot. Both tubes are then immersed in ice water for 10 minutes and subsequently warmed in a water bath for 30 minutes at 37° C. In a positive response, hemolysis is found in the blood taken from the patient, whereas the serum in the control tube is clear.

A more satisfactory test (modified from MacKenzie) is performed as follows:

All syringes, tubes, and salt solutions used in carrying out the test are warmed. About 10 ml blood are taken from the arm vein of the patient. Half of this blood is placed in a dry, clean centrifuge tube, allowed to clot, and centrifuged; the serum is then removed. The remainder is placed in a bottle containing anticoagulant and some of these red cells are washed three times in warm 0.85% so-

drum chloride solution. Then a 5% suspension of cells is made. About 2 ml of the suspension will be required.

Blood is obtained from a normal individual of the same blood group as the patient and is prepared in the same way that the patient's blood is prepared. Complement is prepared by making a 1:10 dilution of fresh guinea pig serum.

Six tubes are placed in a rack and 0.2 ml of complement is measured into each; 0.1 ml of saline solution is pipetted into tubes 1, 2, 3, and 4 and 0.6 ml is pipetted into tubes 5 and 6; 0.5 ml of the patient's serum is measured into tubes 1 and 3, and an equal volume of control serum is measured into tubes 2, 3, and 4. Then 0.2 ml of the suspension of patient's red cells is placed in tubes 1, 4, and 5 and the control red cells are placed in tubes 2, 3, and 6. The set of six tubes is then immersed in ice water for 10 to 30 minutes, after which it is warmed in a 37° C water bath for 30 minutes. When the reaction for cold hemolysis is positive, hemolysis will be found in tubes 1 and 3, whereas the other tubes will be clear.

## Treatment

Treatment for syphilis is given when this disease is present; clinical improvement of the PCH appears to occur in the majority of such patients.<sup>217</sup> Failures have been reported, however, and in some patients the reaction to the D-L test has remained positive even though the hemolytic disease has been cured.<sup>217</sup> No specific therapy is available for patients suffering from non-syphilitic forms of PCH, but in those with PCH accompanying acute viral infections the disorder is usually of short duration and no therapy is required. Avoidance of cold and damp is the only effective measure for individuals suffering from chronic idiopathic PCH. There seems to be no good indication for the use of steroids in the treatment of any of these patients. Immunosuppressive drugs, such as cyclophosphamide, have, to our knowledge, not been tried, although they would constitute a logical choice in patients suffering from chronic PCH of unknown cause.

Antihistamines and steroids are useful in the control of urticarial lesions.

crescents, helmets, triangles, and/or microspherocytes (Fig. 28-1). These morphologic features readily differentiate the red cell fragmentation syndromes from other acquired hemolytic anemias.

Hemolytic anemias due to red cell fragmentation have been associated with abnormalities of the heart and great vessels, or with disease of small vessels (Table 28-1). These two groups differ in regard to etiology, pathogenesis, and prognosis, and require different approaches to therapy. They will therefore be discussed separately.

### Red Cell Fragmentation Due to Cardiac Abnormalities

#### Etiology

Soon after the advent of open heart surgery it became apparent that the postoperative course of some patients was complicated by the development of anemia of varying severity. The earliest observations were made in recipients of Hufnagel ball valves that had been inserted into the thoracic aorta.<sup>39,40</sup> Experiments with Hufnagel valves in dogs subsequently established intravascular hemolysis as the cause of the anemia.<sup>45</sup> Unfortunately, none of these workers studied the morphologic appearance of the erythrocytes in detail and the discovery of fragmented red cells as

WHEN red cells are subjected to excessive physical trauma within the cardiovascular system they may undergo premature fragmentation and lysis. Sometimes the insult is sufficiently severe to cause significant intravascular hemolysis with hemoglobinemia, hemoglobinuria, hemosiderinuria, and shortened red cell survival. The hallmark of this type of hemolysis is the fragmented red cell or *schistocyte* (page 543). This is a cell that has successfully resealed its membrane after losing part of its envelope and cytoplasm, and continues to circulate for a short time before being removed by the reticuloendothelial system. Schistocytes may take the form of

Fig. 28-1. Schisocytes in red cell fragmentation syndromes. A, B, and C are from patients with artificial heart valves. D, E, and F are from patients with microangiopathic anemia.

a characteristic feature of this type of anemia was not made until 1961, when Sayed, Dacie, and their coworkers reported these morphologic alterations in a patient who had developed severe and persistent intravascular hemolysis after repair of an ostium primum defect with Teflon.<sup>41</sup> Since then many reports have described a variety of patients in whom fragmented erythrocytes or clinically detectable intravascular hemolysis was associated with a wide variety of structural defects of the heart or great vessels (Table 28-1).

Surgically inserted prosthetic devices have furnished the most striking examples of red cell fragmentation. These include valves of the ball-and-basket variety,<sup>4,19,27,32,37,38</sup>

disk-type prostheses,<sup>52</sup> Teflon leaflets,<sup>51,57</sup> and synthetic valves made of Dacron cloth impregnated with rubber,<sup>12</sup> as well as valve homografts<sup>39</sup> and autograft valvoplasties.<sup>11,46</sup> Most of the valve prostheses associated with hemolytic disease have been of the aortic variety, but occasional cases of hemolysis due to mitral valve replacement<sup>26,52</sup> and unsuccessful mitral valvoplasty<sup>53</sup> also have been reported.

Intracardiac patch repairs of various types also can lead to intravascular hemolysis<sup>41,43,50</sup>; most reported cases have occurred in patients with Teflon patches used in the repair of ostium primum defects. In addition, intravascular hemolysis has been noted in a

aortic valve disease, especially aortic stenosis, but occasionally red cell fragmentation has been observed in patients with mitral valve involvement. Intravascular hemolysis also has been reported in a patient who had a ruptured aneurysm of the sinus of Valsalva,<sup>16</sup> in one with coarctation of the aorta,<sup>36</sup> and in another with coarctation and a bicuspid aortic valve.<sup>51</sup> When hemolytic disease accompanies valvular heart disease for which surgical treatment has not been given, it is rarely severe and in most affected patients the hemolysis is minor and clinically unimportant.

### Incidence

The exact incidence of intravascular hemolysis due to intracardiac prostheses is difficult to determine, since it undoubtedly depends on the severity of the defect, the expertise of the surgeon, and the sensitivity of the methods being used to study patients for the presence of hemolysis. Clinically significant hemolytic disease has been reported in 5 to 25% of patients with various types of valvular prostheses,<sup>24, 27</sup> usually replacing defective aortic valves, and in about 5% of patients with Teflon repairs of ostium primum defects.<sup>209</sup> The incidence of clinically detectable hemolysis in patients with mitral valve prostheses is considerably lower. When sensitive techniques such as red cell survival,<sup>3, 20 56</sup> haptoglobin levels,<sup>1, 3 7, 49</sup> or lactate dehydrogenase isoenzyme levels<sup>1, 23</sup> have been used, however, it has been found that a majority of patients with aortic valvular prostheses give evidence of mild intravascular hemolysis.<sup>1, 3, 7, 20, 56</sup>

The incidence of intravascular hemolysis in selected patients with aortic valve disease who have not been operated upon has ranged from about 5%<sup>28</sup> to 67%<sup>5</sup> as studied by <sup>51</sup>Cr survival techniques,<sup>5, 20, 28</sup> haptoglobin levels,<sup>7, 49</sup> and lactate dehydrogenase isoenzymes.<sup>23</sup> Undoubtedly, the severity of the valvular disease is an important variable.

### Pathogenesis

Red cell survival studies have clearly shown that the red cell fragmentation associ-

patient with tetralogy of Fallot who had a Dacron tube inserted between the aorta and the pulmonary artery.<sup>48</sup> When the artificial channel became obliterated by thrombus, the hemolytic process stopped.

Although red cell fragmentation is most strikingly associated with intracardiac surgical procedures, intravascular hemolysis due to similar mechanisms also has been described in many patients with valvular heart disease who have not been treated surgically.<sup>5, 8, 14, 20, 49, 55</sup> Most commonly this has been noted in patients suffering from severe

ated with intracardiac abnormalities is due to an extracorporeal defect.<sup>19,27,41,43,44</sup> Several mechanisms have been postulated to account for the intravascular nature of the hemolysis and the appearance of the characteristic fragmented cells.

*Direct mechanical trauma*, for instance by the closure of prosthetic valves, has been postulated; it is known to occur in other conditions such as march hemoglobinuria,<sup>253</sup> but since many patients with prosthetic valves do not have clinically significant hemolysis, it is unlikely that valve closure itself is responsible for much mechanical disruption of red cells. It is also unlikely that the presence of prosthetic materials per se contributes to red cell fragmentation,<sup>27,30,45</sup> although bare Teflon has been found at reoperation in some patients.<sup>41,50</sup> It would seem more likely that both the hemolysis and the lack of endothelialization depend on the presence of a third factor, such as turbulence, as discussed below.

Since the hemolysis of microangiopathic hemolytic anemia is related to the deposition of fibrin in small blood vessels (page 938) it has been postulated that similar mechanisms may be operative in the hemolytic anemia associated with cardiac defects. Fibrin deposition within the heart is not a common finding at autopsy, however<sup>27</sup>; in addition, only very fine fibrin strands are capable of fragmenting red cells (page 939), and it is unlikely that such thin fibrin threads could survive, for example, in the turbulence of the left ventricular outflow tract.

A positive reaction to the direct Coombs' test has been observed in a few patients with prosthetic valves<sup>22,33,34</sup> and occasionally in patients with severe aortic valve disease in the absence of surgical intervention.<sup>55</sup> It has been suggested that mechanical damage may have exposed subsurface antigens which then elicited the production of autoantibodies; or transfused lymphocytes may have established a mild graft-versus-host syndrome.<sup>34</sup> However, when the antibody is eluted it behaves as a panagglutinin, reacting with all normal cells tested. Thus it is unlikely that the antibody is specific for hidden determinants or that it is the result of graft-versus-host dis-

ease. Neither is the foreign material used during surgical procedures responsible for the development of autoantibodies.<sup>34</sup>

The most common feature in recorded cases of hemolysis following the insertion of prosthetic devices has been the existence of some form of hemodynamic defect, such as regurgitation through or around aortic prostheses,<sup>27</sup> mitral insufficiency in patients whose AV canal defects had been repaired by Teflon patches,<sup>43</sup> and regurgitation of blood through a Dacron tube inserted between the aorta and the pulmonary artery in a patient with tetralogy of Fallot.<sup>48</sup> Extreme turbulence is a common factor in all of these patients and it has been suggested<sup>20</sup> that this is responsible for hemolysis, rather than the direct buffeting of red cells against unphysiologic obstacles. It has been shown that a shearing stress in excess of 3000 dynes/cm<sup>2</sup> can easily cause mechanical hemolysis in vitro,<sup>31</sup> and that turbulence resulting in this degree of stress may readily develop in the presence of regurgitant defects between the aorta and the left ventricle in situations where the lumen of the aortic prosthesis is small relative to the stroke volume, or when the ball of a ball valve is large relative to the diameter of the aorta. Regurgitant jets through clefts in the mitral valve may establish similar areas of turbulence.

### Clinical Manifestations

There are no distinctive clinical features, with the exception of those related to pre-existent heart disease or cardiac surgery. Sometimes the development of hemolysis coincides with severe deterioration of cardiac function because of the tear of a valve cusp, or the loosening of valve attachments. When the hemolysis is clinically significant, jaundice frequently is obvious, but hemoglobinuria may not be detectable by the naked eye.

### Laboratory Findings

The blood picture varies widely, depending on the severity of the hemolytic process. The hemoglobin level may be normal if the hemolysis is compensated; or it may be ex-

tremely low. Most cells are normocytic and normochromic, although macrocytosis and polychromatophilia will be present in association with a brisk reticulocytosis. When hemolysis and hemosiderinuria have been prolonged, hypochromia due to iron deficiency may develop. The characteristic red cells, however, are the *fragmented erythrocytes* or *schistocytes* (Fig. 28-1), which are identical to those present in patients with microangiopathic hemolytic anemia (see below). The number of fragmented cells seen in the blood smear directly reflects the severity of the hemolytic process and in smears from patients with mild cases none may be apparent.<sup>13</sup> The *bone marrow* shows increased erythropoietic activity and, if the hemolysis is of long standing, the marrow iron stores may be depleted due to hemosiderinuria.

The serum *bilirubin* is slightly or moderately raised and the plasma hemoglobin level may be elevated. The haptoglobins are depleted and methemalbumin is found in the plasma. Lactate dehydrogenase levels, and especially those of isoenzyme LDH 1, are probably always elevated, at least in patients with prosthetic devices.<sup>13, 23</sup>

Hemoglobinuria and hemosiderinuria are found in patients with the more severe cases and may be constant. Hemosiderinuria is present in many patients when hemoglobinuria is not detectable.

The reaction to Coombs' test usually is negative, but occasionally the reactions are positive (see above).

## Treatment

When it is necessary and feasible the cardiac defect should be repaired; only occasionally does the condition causing the hemolysis improve spontaneously.<sup>11</sup> Since the severity of the hemolytic process is increased by physical activity,<sup>42</sup> bed rest is mandatory during acute exacerbations. When red cell fragmentation is accompanied by a positive reaction to Coombs' test, steroids may reduce the degree of hemolysis.<sup>34</sup> When iron deficiency has developed because of prolonged hemosiderinuria, iron therapy is of distinct benefit.<sup>37, 53</sup>

## Red Cell Fragmentation in Association with Small Vessel Disease (Microangiopathic Hemolytic Anemia)

In 1952, Symmers<sup>134</sup> introduced the term "microangiopathic hemolytic anemia" to describe a clinical syndrome now commonly referred to as "thrombotic thrombocytopenic purpura" (see below). The term was subsequently popularized by Brain, Dacie, and Hourihane<sup>75</sup> and is now used to designate any hemolytic anemia that is due to red cell fragmentation occurring in association with small vessel disease (Table 28-1).

### Experimental Models of Pathogenesis

In man, microangiopathic hemolytic anemia is usually associated with one of two clinical findings: deposition of fibrin within the microvasculature or severe systemic hypertension. Several experimental models have helped to elucidate the mechanisms of red cell fragmentation under these two conditions.

When intravascular coagulation is induced in rabbits by the infusion of endotoxin<sup>74</sup> or thrombin,<sup>76</sup> the onset of red cell fragmentation and hemoglobinemia is closely linked to the development of renal glomerular thrombosis. The hematologic changes can be prevented by pretreatment with heparin. These findings strongly suggest a link between the deposition of platelet and fibrin thrombi and red cell fragmentation. The rate of fibrin deposition appears to be an important variable: rabbits injected with Arvin, a powerful coagulant derived from Malayan pit viper,<sup>129</sup> only develop intravascular hemolysis when rapid defibrination is produced by large amounts of Arvin. Presumably, smaller fibrin deposits are lysed as soon as they are formed; even with large amounts of Arvin, fibrinolysis does not lag far behind and hemolysis stops quickly, usually within minutes after injection of Arvin. If, on the other hand, fibrinolysis is prevented by the prior administration of  $\epsilon$ -aminocaproic acid (see Chapter 38), con-

tinued hemolysis and marked red cell fragmentation persist for many hours.

Histologic studies associate hemolysis with a loose fibrin network to which red cells adhere.<sup>129</sup> Other *in vitro* experiments have expanded these observations: when red cells are forced through a loose fibrin clot within a slide chamber, they attach to very fine fibrin threads and fold themselves around these razor-sharp strands<sup>78</sup> (Fig. 28-2). As other cells flow past their attached fellows they either cause their release or their fragmentation, often with resealing of the membrane. This resealing results in the formation of the oddly shaped fragments described previously. Similar results are obtained when nylon or glass fibers are used in artificial circuits.<sup>78</sup> This suggests that red cell fragmentation depends on the arrest of individual cells by any obstruction of small dimensions in relation to its own size, with subsequent injury of the arrested cell by the rapidly flowing blood stream. Strands or spikes less than one micron in diameter are particularly prone to produce red cell fragmentation.<sup>78</sup>

Other experimental models have dealt with the role of hypertension in producing red cell

fragmentation. When rats are given desoxycorticosterone and a high salt intake they develop malignant hypertension with widespread degenerative vascular lesions, and, coincidentally, a hemolytic anemia characterized by red cell fragmentation.<sup>141</sup> Closely analogous to the human counterpart of this syndrome, the most anemic animals are those with the most severe vascular lesions. While some fibrin and platelet deposits are seen within the lumen of some vessels, they do not play a predominant role in red cell fragmentation. The striking finding on electron microscopy of arterioles is the close juxtaposition of erythrocytes to endothelial cells, the apparent molding of projections of endothelial cells around the erythrocytes, and the partial penetration of the endothelium by erythrocytes. Red cell fragmentation is thought to be the result of shearing stress from the force of the arterial blood as it moves past red cells that are attached to endothelial projections or have partially penetrated the endothelium. Parallel observations were made in rabbits receiving catecholamine infusions<sup>141</sup>; red cells were shown to be squeezed through the endothelium, and it was

Fig 28-2. Scanning electron micrograph of red cells "clothes lined" over fine fibrin strands, *in vitro* model. Other cells, moving past these trapped erythrocytes may cause their fragmentation. Thicker fibrin strands in background do not cause this injury (From Bull and Kuhn,<sup>77</sup> courtesy of the authors and Henry M. Stratton, Inc.)

suggested that this may be the principal mechanism of red cell fragmentation in this experimental model.

Thus damage to red cells and hemolysis may result either from the intravascular deposition of fibrin or from primary vascular damage produced by severe hypertension or vasoconstriction. In human disease, microangiopathic hemolytic anemia has been found to complicate vascular disease produced by either mechanism. The relative importance of these two, or of other as yet unidentified mechanisms, clearly has a bearing on the nature and effectiveness of therapy, as well as on the ultimate prognosis.<sup>73</sup>

## The Hemolytic Uremic Syndrome

The term "hemolytic uremic syndrome" was first coined by Gasser and his coworkers, in 1955, to describe the fatal association of an acute intravascular hemolytic anemia and renal failure in infants and young children.<sup>91</sup> These authors were also the first to recognize the presence of fragmented erythrocytes ("zerfallene Formen") in at least one of the patients studied. Several hundred patients, some in large series,<sup>93,94,104,111</sup> have been reported since then and the clinical features of the disease are now well defined. Nevertheless, there still is some uncertainty about the cause and pathogenesis of this syndrome and, consequently, the optimal approach to therapy.

### Clinical Manifestations

The hemolytic uremic syndrome characteristically appears suddenly in otherwise healthy infants and children. The highest incidence is in the first year of life, with a peak onset at the age of seven months.<sup>72</sup> After the first year of life, there is a marked decline in the number affected, but sporadic cases have been reported among late teenagers and young adults. The most common antecedent illness is gastroenteritis, but in some patients the onset of anemia and

renal failure is preceded by a brief febrile illness, usually of undetermined origin. Sometimes bacterial,<sup>87,132,133</sup> rickettsial,<sup>116</sup> or viral<sup>193,96,123,127</sup> pathogens have been identified. The occurrence of outbreaks of the disease suggests that particular viruses may sometimes be responsible.<sup>68,93,115,130</sup> In some subjects the hemolytic uremic syndrome has followed immunization against diphtheria, pertussis and tetanus,<sup>85,89,122</sup> polio,<sup>120</sup> measles,<sup>109</sup> or smallpox.<sup>117</sup>

The onset of hemolysis and renal failure may be dramatic with sudden pallor, abdominal pain, vomiting, and the appearance of dark-red or nearly black urine. These manifestations quickly give way to oliguria and, in many patients, total anuria. On *physical examination* the infant usually is pale, slightly jaundiced, and may have purpuric lesions, ecchymoses, and evidence of bleeding from mucous membranes, especially if aspirin has been given during the prodromal illness. Moderate hepatomegaly is common, but splenomegaly is not; the kidneys may be palpable and tender. Various neurologic manifestations may be noted, including drowsiness, convulsions, and transient pareses, but these are not as frequent as in patients with thrombotic thrombocytopenic purpura. An elevated blood pressure is present in about half the patients and helps to differentiate this syndrome from other causes of acute renal failure associated with diarrhea, such as dehydration and renal vein thrombosis.

### Laboratory Findings

The *anemia* often is severe and may be accompanied by moderate polymorphonuclear *leukocytosis*. *Thrombocytopenia* may be marked, but is not invariably present. The lowest platelet counts usually are found in the most anemic patients. The blood smear is distinctive; many fragmented erythrocytes, burr cells, and some microspherocytes contrast with a moderate number of large polychromatophilic cells representing reticulocytes. No intracorpuseular defects are evident and the extraerythrocytic nature of the he-

molytic process may be demonstrated by the markedly shortened survival of erythrocytes from normal donors. The reactions to both the direct and indirect antiglobulin tests are negative, but a few exceptions have been noted.<sup>81,99</sup>

The plasma contains free hemoglobin that is frequently detectable by naked-eye examination. Hemoglobinemia may be marked and correlates with the degree of anemia and the severity of the morphologic changes. Haptoglobins are low or absent and methemalbumin may be detectable spectroscopically. The bilirubin levels usually are only mildly elevated and rarely exceed 2 to 3 mg/dl. The blood urea nitrogen and serum creatinine levels may be very high.

The urine usually contains hemoglobin and hemosiderin in addition to large quantities of other proteins, especially albumin. Microscopically, red cells, white cells, and casts are seen.

In a few patients, prolonged prothrombin times and partial thromboplastin times, low levels of labile clotting factors, and elevated levels of fibrin breakdown products have been found,<sup>84,107,118,123,133,144</sup> but usually the levels of factors V, VIII, and fibrinogen are normal or increased.<sup>66,93,102,110,139</sup> Some workers have demonstrated an increased <sup>131</sup>I-fibrinogen turnover rate, but this has been denied by others.<sup>116a</sup> There is no demonstrable increase in the deposition of <sup>131</sup>I-fibrinogen in the kidneys.<sup>116a</sup>

### Pathologic Changes

The main lesions are found in the kidney,<sup>143</sup> and specifically in the renal glomeruli, some or all of which may be affected. On gross examination the kidneys are swollen and pale, with many "flea-bite" hemorrhages on the surface. Light microscopy confirms the focal nature of the lesions, both between and within individual glomeruli. In the most severely affected glomeruli, these lesions consist of congestion and infarction with hyaline thrombosis of the capillaries. Less affected glomeruli show thickening of capillary walls by eosinophilic, faintly PAS-positive hyaline

material that is deposited between the endothelial cells and the basement membrane, and hypertrophy and proliferation of mesangial endothelial cells. On electron microscopy,<sup>81,143</sup> granular or fibrillar electron-dense material is seen both within the endothelial cells and in the space between the endothelial cells and the basement membrane. Large numbers of platelets also have been identified within the glomerular capillaries.<sup>81</sup> There is evidence to suggest that the material deposited in the glomerular capillary wall consists, at least partially, of fibrin or fibrin derivatives,<sup>81,82,88</sup> as does the hyaline material found on electron microscopy within the endothelial cells.

The afferent glomerular arterioles, and sometimes the interlobular arteries, show fibrinoid necrosis of their walls. Foci of renal cortical necrosis are frequent in severely affected patients.

### Etiology and Pathogenesis

It has been suggested that overt or occult intravascular coagulation may be a central factor in the development of the microangiopathy, and that focal intravascular coagulation may be the cause of the hemolysis and uremia.<sup>72,107,140</sup> Furthermore, it is held that intravascular coagulation may be accelerated by the release of thromboplastic materials from intravascularly lysed erythrocytes.<sup>71</sup> In support of this view, the beneficial effects of early treatment with heparin<sup>68,72,84,95,103,107,118,119</sup> and/or streptokinase<sup>119</sup> have been cited. The hemolysis is attributed to mechanical damage to red cells as they pass over fibrin deposits or projections of abnormal endothelial cells, as discussed earlier in this chapter (page 938). The thrombocytopenia is attributed to the aggregation of platelets in glomerular lesions and to their consumption during the process of low-grade intravascular coagulation observed in some patients.<sup>67</sup> Supporting this view is the observation that, following anticoagulation with heparin, the platelet count usually rises.

The hypertrophy and hyperplasia of phagocytic glomerular epithelial cells appear to be

due to the deposition of fibrin. This is suggested by the presence of hyaline material within endothelial cells and by animal experiments in which intravascular coagulation within the capillaries was triggered by immunologic means.<sup>140</sup> Endothelial proliferation may be so severe as to contribute significantly to the poor glomerular circulation. It is preventable by anticoagulation, which removes the primary cause of the cellular proliferation.<sup>140</sup>

The factors precipitating the development of vascular lesions in children with hemolytic uremic syndrome remain obscure. The association of the syndrome with viral and bacterial infections, and immunizations, as well as the frequent occurrence of this disorder in patients with immune deficiency syndromes,<sup>85 89 93,105</sup> suggests that immunologic reactions, perhaps of a very specific type, may play an etiologic role. Since the pattern of specific immune responses appears to be genetically determined,<sup>112</sup> the occurrence of the hemolytic syndrome in siblings and close relatives,<sup>65,80 93 110</sup> often at intervals of some months or years, is of special interest. It is possible that this pattern reflects an inherited peculiarity, though not necessarily an abnormality, of the immune response.

Soluble immune complexes have been shown to initiate intravascular coagulation in vitro<sup>128</sup> and to produce renal glomerular thrombi in vivo.<sup>104</sup> In experimental models the development of glomerulonephritis can be shown to be associated with "incomplete" immune responses.<sup>92,124</sup> This observation has been proposed as an explanation for the low age incidence of the hemolytic uremic syndrome,<sup>72</sup> as well as the frequent occurrence of the condition in patients with various immune-deficiency syndromes.

## Therapy

At least some of the recent decrease in the mortality of the hemolytic uremic syndrome reflects better general care of patients in renal failure and is not attributable to any specific form of therapy.<sup>110</sup> In isolated cases, for in-

stance, peritoneal dialysis has allowed patients to recover spontaneously after two or more weeks of anuria.<sup>133,136</sup> Similarly, the astute management of fluids and electrolytes, blood transfusions, and the control of hypertension undoubtedly contribute to the survival of patients who are capable of recovering spontaneously if they are given sufficient time.

Many patients have been treated with *heparin*.<sup>68,72,84,93,100,103,107,110,118,119,133,141</sup> No well-controlled trials are available, but the effect of this therapy has often been dramatic, with prompt fall in plasma hemoglobin concentrations, increased platelet count, and improvement in renal function. Failures of heparin therapy have been reported.<sup>93,101a,116a,142</sup> In some patients the dose of heparin may have been inadequate since it has been shown that the amount of heparin needed to bring about the desired effect is larger in patients with microangiopathic hemolytic anemia than in those with other conditions.<sup>72</sup> We have found that minimum doses of 25 U/kg/hr have to be administered and frequently doses of 35 U/kg/hr are needed in order to produce significant prolongation of the clotting time, or to achieve a satisfactory plasma level as measured by protamine neutralization. If the clotting time is prolonged prior to therapy because of ongoing intravascular coagulation or for other reasons, it cannot be used as a guide to the adequacy of therapy. In some centers, heparin is never used.<sup>137</sup>

Theoretically, fibrinolytic agents should give good results, and favorable responses to streptokinase, usually in conjunction with heparin, have been reported.<sup>69,119</sup> Complications, especially bleeding, are common with these agents (Chapter 38) and controlled trials are not available.

*Adrenocorticoids* have been given to many patients, occasionally with apparent benefit,<sup>123</sup> but most authors are not convinced of the value of this form of therapy.<sup>68 93,100,101 110,126</sup> Indeed, it has been suggested that steroids may be harmful in patients with intravascular coagulation disorders.<sup>70 110</sup>

## Prognosis

In one study the overall mortality of 250 infants and children with the hemolytic uremic syndrome, who were cared for between 1957 and 1967, dropped from 23% among the first 150 patients to 5% in the last hundred.<sup>93</sup> This probably reflected recognition of milder forms of the disease as well as improved care. Unfavorable prognostic factors include (1) the severity of the acute phase of the disease,<sup>93</sup> (2) the duration of anuria,<sup>93</sup> and (3) the extent of glomerular damage<sup>72</sup>; 80 to 100% of glomeruli are affected in patients who die, whereas 50% or fewer glomeruli have been involved when renal biopsy specimens were obtained from children who recovered.

## Thrombotic Thrombocytopenic Purpura (TTP) (Moschkovitz Syndrome<sup>174</sup>)

Thrombotic thrombocytopenic purpura is a serious but uncommon disorder of young adults. It is characterized by hemolytic anemia, thrombocytopenia, neurologic signs, renal disease, and fever. The clinical manifestations are caused by widespread disease of small blood vessels and appear to merge pathologically and clinically with those of the hemolytic uremic syndrome of infancy and childhood. There are, however, important *clinical differences*: TTP is most frequently seen in young adults, it has a tendency to involve more organ systems, and has a much higher mortality rate than the hemolytic uremic syndrome. Several hundred cases of the disease have been reported and the pertinent clinical data have been summarized in a number of reviews.<sup>152,159-185,188</sup>

## Clinical Manifestations

Although TTP may occur in the very young<sup>171</sup> and the very old, most patients are between 10 and 40 years of age, with a peak incidence in those in the third decade of life. Females are more frequently affected than males (3:2). The chief clinical manifestations

in a large series of subjects are summarized in Table 28-2. It is obvious that virtually all patients have fever, hemorrhagic manifestations, anemia, neurologic signs, and renal disease.

The cause of the fever is not known but it does not appear to be due to superimposed infections. *Hemorrhagic manifestations* usually take the form of petechiae and ecchymoses of the skin, but retinal hemorrhages, epistaxis, bleeding from the gastrointestinal tract, and gross hematuria also are frequently present. Virtually all patients (96%)<sup>152</sup> have *thrombocytopenia*. Anemia is a constant feature and many patients are clinically jaundiced.

*Neurologic manifestations* constitute the initial symptom in about 50% of these patients. The most common presenting signs are mental changes such as confusion, delirium, and altered states of consciousness, or hemiparesis.<sup>185</sup> Other findings include aphasia, seizures, hemisensory changes, ataxia, and field defects. While it is generally stated that the neurologic abnormalities are typically remittent and subject to sudden change,<sup>152</sup> it was found that fewer than half of all patients showed significant improvement from their initial neurologic defects.<sup>185</sup> The frequency of the neurologic manifestations can be attributed to the common and

Table 28-2. Clinical Manifestations of Thrombotic Thrombocytopenic Purpura (TTP)

	Cases	Percent
Fever	237/243	98
Pallor or anemia	246/256	96
Hemorrhagic manifestations	241/251	96
Neurologic manifestations	250/271	92

striking involvement of the small vessels of the cortical gray matter and the brain stem.

*Renal disease* is present in most patients and is due to hyaline occlusion of capillaries and arterioles,<sup>88</sup> and proliferative changes within the glomeruli.

Other clinical manifestations include abdominal pain due to pancreatitis<sup>174a</sup> or occlusion of visceral vessels, hepatomegaly (25%), and splenomegaly (20%).<sup>152</sup> Occasionally, Raynaud's phenomena are found.

### Laboratory Findings

The hemoglobin is below 10.5 g/dl in virtually all subjects, and less than 5.5 g/dl in about a third. There is an appropriate reticulocytosis in most of the patients, and normoblasts are frequently found in the blood. The most characteristic morphologic abnormalities are the bizarre, distorted, and fragmented red cells (schistocytes, Fig. 28-1). The reaction to Coombs' test is negative.

Occasional prolongation of prothrombin time and decreased fibrinogen levels have been noted and increased titers of fibrin breakdown products have been reported,<sup>162, 165, 168, 172</sup> but in most patients there is no evidence of disseminated intravascular coagulation.<sup>152, 165, 168</sup> *Thrombocytopenia* is an almost constant finding; platelet counts of 10 to 120  $\times 10^9/l$  were reported in 216 of 224 patients collected in one study.<sup>132</sup> The reaction to the tourniquet test usually is positive, the bleeding time is prolonged, and clot retraction is poor. Increased utilization, rather than decreased production, is the probable cause of the thrombocytopenia.

*Leukocytosis* is present in about one half of all these patients, and some have white blood cell counts in excess of 20.0  $\times 10^9/l$ .<sup>152</sup> In addition, a considerable "left shift" may be seen in the blood, with the appearance of immature granulocyte precursors.

The bone marrow shows erythroid hyperplasia and a normal or increased number of young megakaryocytes with smooth borders.

Elevated unconjugated bilirubin levels are found in most patients and may be accom-

panied by elevations in plasma hemoglobin and decreased levels of haptoglobin, suggesting intravascular destruction of red cells as the most likely cause of the hemolysis. Cross-transfusion studies confirm the extracorporeal nature of the defect leading to hemolysis.<sup>183</sup>

Electroencephalographic and electrocardiographic abnormalities have been reported.<sup>152</sup>

### Pathologic Changes

At postmortem examination, characteristic capillary arteriolar occlusions may be seen in the heart, brain, kidneys, pancreas, and adrenal glands, and, to a lesser extent, in virtually all other organs of the body.<sup>152, 168, 170</sup> The nature of the occluding material has not been completely defined, but fibrin components<sup>82, 89</sup> have been identified by immunofluorescent techniques. Other prominent changes include subintimal deposition of similar material,<sup>88, 163</sup> as well as proliferation of endothelial cells.<sup>163</sup> Some authors regard the specific location of vascular lesions at arteriocapillary junctions, with aneurysmal dilatation of weakened vessel walls, as being characteristic of thrombotic thrombocytopenic purpura,<sup>168, 175</sup> but others have found similar lesions in patients with disseminated intravascular coagulation (DIC).<sup>190</sup>

### Etiology and Pathogenesis

Although multiple small thrombi are responsible for the clinical manifestations of TTP, the reason for their development is totally obscure. There is little laboratory evidence to support the contention that the thrombi are manifestations of a DIC syndrome. Some investigators have demonstrated disseminated intravascular platelet aggregation, rather than thrombi, and claim that this may be the cause of vascular obstruction.<sup>171b</sup> Focal damage of vessel walls may be the primary event and intravascular thrombi and arteriolar aneurysms may be secondary phenomena.<sup>168</sup> The cause of the vessel wall damage is equally obscure. Associated drug allergies,<sup>152</sup> rickettsial

infections,<sup>116</sup> vaccinations,<sup>156a</sup> and autoimmune disorders such as lupus,<sup>154,167,169,184</sup> Sjogren's syndrome,<sup>187</sup> polyarteritis,<sup>75,189</sup> and other forms<sup>172</sup> have been suggested as the underlying causes of the vascular pathologic state, but these associations are rare. Positive reactions to serologic tests for syphilis were obtained in nine of 73 patients; in five of these the reactions may have been biologically false positive ones.<sup>152</sup> The simultaneous occurrence of fatal TTP in a married couple<sup>191</sup> and in two sisters who shared the same house<sup>177</sup> strongly suggests an environmental influence.

### Therapy

Whatever their pathogenesis, multiple small thrombi are responsible for the clinical manifestations of TTP in most cases and rational therapy requires an attempt to block their formation. *Heparin* has been used for this purpose, but it has yielded conflicting results. Both success<sup>150,158,179,180</sup> and failure<sup>149,157,158,165</sup> have been reported. Patients who appear to have benefited have usually received other medications concurrently. No controlled trials are available and it is therefore impossible to judge the true efficacy of heparin.

*Dextran* coats vascular surfaces<sup>156</sup> and platelets<sup>181</sup> and interferes with platelet aggregation, as judged by prolongation of bleeding time.<sup>166</sup> The use of dextran has been reported to have been attended with *apparent* success in the therapy of purpura fulminans<sup>176</sup> and TTP,<sup>168</sup> but these reports need confirmation. Low molecular weight dextran,<sup>158</sup> in contrast to clinical dextran,<sup>168</sup> was of no benefit to one patient with TTP.

If platelet aggregation is the cause of the vascular occlusions,<sup>174b</sup> therapy with drugs which inhibit platelet aggregation, such as aspirin and dipyridamole (Chapter 9), may be of benefit. Success has been reported in a few patients.<sup>151</sup>

Large doses of *adrenocortical steroids* have been used in the therapy of TTP, but did not, by themselves, appear to alter the course of the disease. A review of 46 patients so treated

revealed that only nine of these were still alive at the time of the review.<sup>152</sup>

It has been suggested that *splenectomy*, especially in combination with steroid therapy, may give much better results than either treatment alone; thus, in one series, five of seven moribund patients responded dramatically to this form of therapy,<sup>153</sup> although two subsequently died in a relapse. Others have also reported good success with splenectomy and steroids.<sup>152,164,182,183</sup>

### Prognosis

TTP is a most serious disease and usually runs a rapidly progressive and fatal course. Most patients (80%) are dead within three months, and fewer than 10% survive for more than a year.<sup>152</sup> In actual fact the number of patients who survive an attack of TTP may be much lower, since many of the long-term survivors have been shown *not* to have classical TTP. Furthermore, it is likely that more successes than failures are reported in the medical literature.

## Disseminated Intravascular Coagulation (DIC)

Microangiopathic hemolytic anemia also is associated with a variety of disorders characterized by disseminated intravascular coagulation (Chapter 38), including that associated with sepsis,<sup>238,239</sup> purpura fulminans,<sup>218</sup> heart stroke,<sup>245</sup> and abruptio placentae.<sup>67,201</sup> In all of these clinical conditions, red cell fragmentation appears to be due to the deposition of fibrin within the microvasculature. Fortunately, hemolysis often is not severe and may not contribute significantly to the morbidity of the disease. As the underlying disease comes under control with appropriate therapy, the fragmentation of red cells also ceases.

## Microangiopathy Associated with Immune Mechanisms

Microangiopathic hemolytic anemia may also be a feature of diseases in which the

microvasculature is damaged by immune mechanisms. This includes lupus erythematosus,<sup>75</sup> acute glomerulonephritis,<sup>75,99</sup> and the homograft reaction,<sup>213</sup> all of which are characterized by the presence of antigen-antibody complement complexes within selected areas of the microvasculature.<sup>223,229</sup> Red cell fragmentation also has been observed in association with polyarteritis nodosa,<sup>75,139</sup> scleroderma,<sup>210</sup> and Wegener's granulomatosis.<sup>207</sup> While the immunologic nature of the latter diseases is as yet poorly defined<sup>211</sup> this is, nevertheless, likely. Fibrin deposits have been demonstrated in the vascular lesions of patients with these diseases.<sup>216,234</sup>

Antigen-antibody-complement complexes readily trigger the coagulation cascade,<sup>140</sup> probably through an effect on platelets.<sup>193</sup> As a result, fibrin is deposited and this stimulates the proliferation of endothelial cells.<sup>140</sup> It is likely that both the fibrin deposition and the endothelial changes are responsible for the red cell fragmentation (see page 938).

Microangiopathic hemolytic anemia has also been reported in association with *systemic amyloidosis* (Chapter 53).<sup>221</sup>

## Giant Hemangiomas and Hemangioendotheliomas

Microangiopathic hemolytic anemia has been described in patients with giant hemangiomas<sup>220,237</sup> and in those with hemangioendotheliomas of the liver.<sup>195</sup> There is good evidence that local coagulation in the abnormal blood vessels plays a role in the red cell fragmentation.<sup>220</sup> Irradiation of the hemangioma has been found to abolish red cell fragmentation and the associated thrombocytopenia.<sup>220</sup>

## Disseminated Carcinoma

Microangiopathic hemolytic anemia has been observed in a large number of patients with disseminated malignant disease involving the stomach,<sup>75,202,214,227,243</sup> colon,<sup>214</sup> pancreas,<sup>214</sup> breast,<sup>202</sup> lung,<sup>75,202</sup> pros-

tate,<sup>75</sup> and other sites.<sup>214</sup> On the basis of coagulation studies,<sup>222,227,243</sup> many of these patients were thought to have intravascular coagulation and some were shown to have markedly increased rates of fibrinogen catabolism.<sup>67</sup> In other patients the red cell fragmentation was attributed to widespread occlusion of the pulmonary vasculature by tumor emboli, but this mechanism, if indeed operative, would not account for the red cell fragmentation found in a majority of these patients. Among 12 patients with microangiopathic hemolytic anemia that occurred in association with metastatic carcinoma originating in the stomach, breast, or lung, tissues were available for study from 11 and all 11 were found to have mucin-secreting adenocarcinomas.<sup>202</sup> It was suggested that mucin was directly responsible for the induction of intravascular coagulation by mechanisms that had been demonstrated *in vitro*. Of these 12 patients, 10 had been thrombocytopenic, all had greatly increased rates of fibrinogen catabolism, and fibrin breakdown products were found in the serum. In addition, hyaline thrombi were demonstrated in various tissues from several of these patients. It was suggested that the microangiopathic hemolytic anemia was secondary to intravascular coagulation and this in turn was brought about by thromboplastic substances released by tumor cells.<sup>202</sup>

## Eclampsia and Preeclampsia

Acute intravascular hemolysis has long been known to complicate the clinical course of patients with eclampsia and severe preeclampsia.<sup>236</sup> More recently, red cell fragments have been observed in such patients.<sup>242</sup> Hypertension may itself lead to red cell fragmentation and hemolysis by mechanisms discussed earlier (page 939), but microangiopathic hemolytic anemia has been shown to precede the development of hypertensive retinopathy in some subjects,<sup>200</sup> and therefore factors other than hypertension may be important. The deposition of fibrin in endothelial cells or between the endothelial cells and the basement membrane suggests that intra-

vascular coagulation plays an important role in the renal pathologic state of preeclampsia<sup>217,231,238</sup> and, hence, in the pathogenesis of red cell fragmentation. The frequent occurrence of thrombocytopenia and cryofibrinogenemia in preeclamptic patients has been cited as evidence for a low-grade process of intravascular coagulation.<sup>200</sup> Pregnancy also has been observed to render the experimental animal more susceptible to the development of the generalized Schwartzman reaction.<sup>232,233,249</sup> Gamma globulin and complement have not been demonstrated within the fibrin deposits,<sup>231</sup> however, and the reason for the intravascular coagulation in these patients remains obscure.

In one review of 14 patients with preeclampsia and intravascular hemolysis<sup>200</sup> the hemoglobin was found to range between 4.2 and 10.5 g/dl (median 6.5 g/dl) and all patients were thrombocytopenic (7 to  $120 \times 10^9/l$ , median 52). The reticulocyte count was inappropriately low in several patients. Pigmentary evidence of intravascular hemolysis was reported in nine, and fragmented red cells were noted in six. Fibrinogen levels were measured in six patients and were found to be normal in five and nearly normal in another. In nine of the 14 patients the diastolic blood pressures were above 100 mm Hg, but in five significant hemolysis occurred in the absence of elevated pressures (130/80 to 160/90). Furthermore, in some patients with hypertensive retinopathy, hemolysis began while the fundi were still normal. All patients had proteinuria and increased blood urea levels. The maternal mortality rate was 64%, and the perinatal mortality was 44%. Only one patient has been reported in whom the hemolysis and thrombocytopenia decreased when heparin therapy was given.<sup>200</sup>

### Malignant Hypertension

An association between red cell fragmentation and malignant hypertension was first recorded by Dacie in 1954,<sup>73</sup> and has since then been confirmed in many other studies.<sup>75,197,205,226,241</sup> Red cell fragmentation

was found in 16 of 24 patients with malignant hypertension, and 10 of these patients also had platelet counts of  $100 \times 10^9/l$  or less.<sup>226</sup> None of these changes was seen in 63 patients with hypertension in the absence of retinal hemorrhages and exudates.

The pathogenesis of microangiopathic hemolytic anemia in malignant hypertension is poorly understood. Most authors attribute the hemolysis to the presence of fibrinoid necrosis within the arterioles,<sup>73</sup> which in turn appears to depend on the presence of hypertension. It has been suggested that subsequent hemolysis may aggravate the arteriolar lesions by producing additional intravascular coagulation.<sup>199,226</sup> Alternatively, the deposition of fibrin, aided by the clot-promoting properties of lysed red cells, may itself underlie the pathogenesis of the malignant phase of hypertension.<sup>226</sup> However, red cell fragmentation is not a constant feature of malignant hypertension,<sup>226</sup> and the fragmentation of red cells may be brought under control by the simple expedient of lowering the blood pressure appropriately,<sup>197</sup> thereby suggesting that hypertension is the cause, rather than the result, of the red cell fragmentation.

### March Hemoglobinuria

March hemoglobinuria is a hemolytic disorder in which transient hemoglobinemia and hemoglobinuria develop in susceptible individuals after strenuous exercise of a kind that involves forceful contact of the body with a hard surface. While red cell fragmentation is not seen, the condition carries all the hallmarks of acute intravascular hemolysis, which presumably is due to the mechanical disruption of circulating red cells. The condition appears to be relatively rare: reports of fewer than 100 cases have been published since Fleischer<sup>256</sup> described the first case in 1881,<sup>253</sup> but clinically inapparent hemoglobinemia may be much more common.<sup>259</sup>

### Clinical Manifestations

With rare exception,<sup>257,261</sup> march hemoglobinuria is confined to males,<sup>253</sup> most com-

monly in those in their late teens or early twenties. The age and sex distribution may reflect the more frequent participation of young males in severe and prolonged exertion. In most subjects, hemoglobinuria is precipitated by prolonged marches or competitive running, but the syndrome has also been described in conga drum players,<sup>262</sup> following karate exercises,<sup>266</sup> and in an individual suffering from dementia praecox who had cultivated the unusual habit of slapping his forehead violently for periods of 20 to 30 minutes.<sup>255</sup>

Passage of red or dark urine after physical exertion is often the only complaint. Occasionally there may be nausea; vague pains in the abdomen, back, or thighs; or a burning feeling in the soles of the feet. Hemoglobinuria characteristically occurs immediately after exercise and lasts for a few hours only. It is most common at the beginning of an athlete's running career or on resumption of road training.<sup>253</sup> Attacks may recur for several weeks or months, rarely for a few years, but may also remit spontaneously despite continuing exercise.

Clinical findings are usually insignificant. Mild transient jaundice is rarely present, even immediately following attacks of hemoglobinuria. Occasionally the liver or spleen is palpably enlarged. On cystoscopy, red-colored urine is seen to issue from both ureteric orifices.<sup>253</sup>

### Laboratory Findings

Anemia is uncommon, as less than 1% of the patient's circulating red cells are hemolyzed in an average paroxysm.<sup>253,264</sup> The blood smear does not contain fragmented red cells,<sup>253</sup> although polychromatophilia and a mild reticulocytosis may follow repeated hemolytic episodes. Reactions to osmotic and mechanical fragility tests are normal.<sup>259</sup>

The hallmarks of intravascular hemolysis include a raised serum hemoglobin value, lowered serum haptoglobin, and sometimes methemalbuminemia. The bilirubin rarely exceeds 2 mg/dl. Serum lactic dehydrogenase levels may be elevated.<sup>261</sup> The urine contains

hemoglobin, and after recurrences it may contain hemosiderin. Albuminuria and abnormalities of the urine sediment have been noted,<sup>264,264</sup> but permanent renal impairment is rare; acute tubular necrosis has been reported in one patient.<sup>263</sup>

### Differential Diagnosis

March hemoglobinuria must be differentiated from myoglobinuria (Chapter 20) and from other causes of hemoglobinuria such as paroxysmal cold hemoglobinuria (Chapter 27) and paroxysmal nocturnal hemoglobinuria (Chapter 29). In the latter, hemoglobinuria may be aggravated by exercise. The red color of the urine may suggest porphyria (Chapter 32).

### Etiology and Pathogenesis

The cause of the intravascular hemolysis is not entirely clear, but several observations of interest have been made. (1) Hemoglobinuria usually follows exercise on a hard floor or roadway and does not occur when the same individual uses a grass or cinder track or engages in other strenuous exercise such as swimming or cycling.<sup>258</sup> (2) Patients suffering from march hemoglobinuria frequently have a very heavy stride. (3) Hemoglobinuria can be prevented by the use of shoes with thicker and more resilient soles than those usually worn.<sup>251</sup> Thus it was postulated that susceptible individuals destroyed red cells in the soles of their feet while running.<sup>253</sup> (4) Confirmation came from the ingenious experiments of Davidson<sup>252</sup> who inserted polyvinyl tubes containing blood into the running shoes of susceptible individuals and showed that they destroyed their own and control blood at approximately the same rate, and to a much greater degree than control subjects running on the same surface. Whether hemolysis is entirely attributable to the type of exercise and the style of running or whether other factors make the red cells of some people particularly susceptible to hemolysis is not clear. It has been suggested that susceptible individuals may suffer from abnormal

hemolysis with ordinary activity as well,<sup>250,264</sup> but no specific cellular or vascular defects have been identified.

The self-limited nature of the attacks has been attributed to the increased mechanical fragility of old erythrocytes.<sup>265</sup> Following elimination of susceptible cells, the rate and degree of destruction of the remaining younger cells may be too low to cause further hemoglobinuria.<sup>251</sup>

## Therapy

No specific therapy is available. Attacks may be prevented by wearing shoes with more resilient soles and by changing to a less traumatic running style.

## Paroxysmal Nocturnal Hemoglobinuria (PNH)

Etiology and Pathogenesis  
 Clinical Manifestations  
 Laboratory Findings  
 Differential Diagnosis  
 Treatment  
 Course and Prognosis

**P**AROXYSMAL nocturnal hemoglobinuria, also known as the Marchiafava-Micheli syndrome, is an uncommon disorder of insidious onset and chronic course. It is characterized, in the classic case, by attacks of intravascular hemolysis and hemoglobinuria, which occur chiefly at night. In a majority of patients, however, the classic pattern is not observed; in these, PNH may be manifested by chronic intravascular hemolysis without a distinct nocturnal pattern, or by pancytopenia, iron deficiency, or recurrent thrombotic episodes. Hemolysis in PNH occurs because of an obscure structural defect of PNH red cells which makes them unusually susceptible to the lytic action of complement.

An excellent account of PNH was given by Strubing in 1882<sup>130</sup>; the disease was subsequently described by Marchiafava and Nazari in 1911 and by Micheli in 1931.<sup>122</sup> By 1953 some 162 cases had been collected in the medical literature.<sup>20</sup> Undoubtedly many cases are overlooked, for the atypical forms are relatively common.

### Etiology and Pathogenesis

Cross transfusion studies have established that PNH is due to an intrinsic abnormality of the red cells,<sup>19</sup> since normal cells survive normally in patients with PNH, while PNH erythrocytes have a shortened life span within the patient or in a normal recipient. Not all PNH red cells are equally susceptible to hemolysis, however, and distinct cohorts of relatively long-lived and very short-lived cells can be readily distinguished by red cell survival studies.<sup>99,117,118</sup> The relative proportions of complement-sensitive and therefore short-lived cells and of complement-insensitive cells vary considerably from patient to patient, and there is good correlation between the numbers of such cells and the clinical course of each patient.<sup>58</sup>

The existence of cell populations with varying sensitivity to lysis in acid or by complement-mediated mechanisms can also be demonstrated by *in vitro* tests.<sup>43,58,115,116</sup> In addition to normal cells and markedly sensitive ones, *in vitro* studies have defined a population of cells with intermediate sensitivity.<sup>115</sup> The majority of patients have either markedly complement-sensitive and normal cells, or markedly complement-sensitive cells and cells of intermediate sensitivity; a smaller number of patients have all three types of cells or normal and intermediate cells only (Fig. 29-1).<sup>115,116</sup> For lysis to occur, complement-sensitive cells require only one twenti-

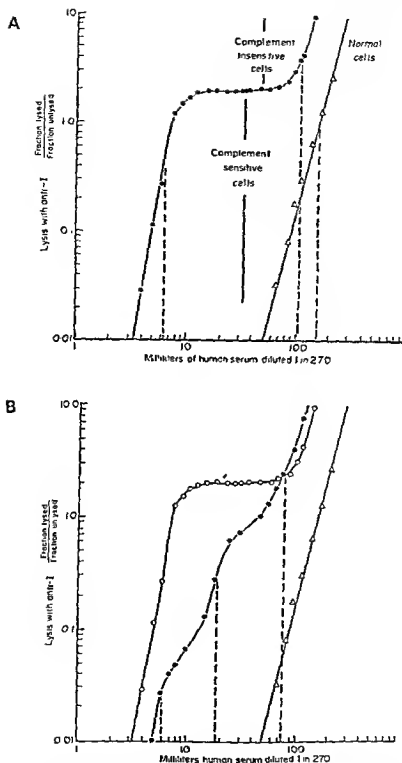

Fig. 28-1. Sensitivity of antibody (anti I) coated red cells to complement mediated lysis, using diluted human serum as a source of complement. The 50% lysis point for each population of cells is indicated (broken lines). A,  $\Delta$ — $\Delta$  Normal donor,  $\bullet$ — $\bullet$  PNH patient with two populations of cells, complement sensitive and insensitive. B,  $\Delta$ — $\Delta$  Normal donor,  $\bullet$ — $\bullet$  PNH patient with three populations of cells, complement sensitive, insensitive, and intermediate.  $\circ$ — $\circ$  PNH patient from A superimposed. (From Rosse,<sup>115a</sup> courtesy of the author and British Journal of Haematology.)

eth the amount of complement needed to disrupt normal cells. Intermediate cells are six to seven times as sensitive as normal cells.<sup>115</sup> The mechanism of erythrocyte lysis by complement is discussed in Chapter 5 (page 203).

Sensitive cells appear to be the product of an abnormal clone of marrow precursor cells<sup>101,115</sup> and do not acquire the defect while circulating.<sup>111</sup> The proportion of abnormal cells is greater in the marrow than in the blood and, among circulating cells, is greatest among young cells, especially reticulocytes.<sup>70,95,99,114,117</sup> If the defect were acquired in the circulation the proportion would be greater among older cells.<sup>115</sup> Erythrokinetic studies have shown that the complement-sensitive population does not gain recruits from the complement-insensitive population.<sup>114</sup> The proportion of sensitive and insensitive cells remains stable for long periods, but population shifts occur during the onset of the disease and in those patients who recover spontaneously.<sup>115</sup>

The increased susceptibility of PNH cells to complement lysis can be demonstrated whether complement activation is induced via the classic complement pathway or via the alternate, properdin-dependent<sup>103</sup> pathway (see Chapter 7, page 333, for a description of both complement pathways). The classic C1-dependent reactions can be induced by antibody,<sup>82,117</sup> whereas lysis in acidified medium (see below) proceeds via the alternate, properdin-dependent pathway.<sup>37,82,115</sup> The alternate pathway also is activated by Naja Naja cobra venom<sup>82</sup> and inulin.<sup>37,82</sup> Lysis induced in media of low ionic strength (see sugar water test and sucrose hemolysis tests, below) probably proceeds via both pathways.<sup>82</sup> The mechanism whereby complement is activated *in vivo* has not been completely delineated but probably involves the alternate pathway predominantly, since neither antibody nor C3 is usually present on circulating cells.<sup>115</sup>

Excessive lysis in acidified human serum is a characteristic feature of PNH cells.<sup>39,41,60</sup> The optimal pH for this reaction is 6.8 to

7.0 with a marked reduction in the degree of hemolysis below or above this range. This contrasts with the much broader range of activity present in antibody-mediated lytic reactions.<sup>60</sup> The optimal temperature for acid hemolysis is between 37° and 40° C; there is a marked reduction in hemolytic activity at higher temperatures due to inactivation of labile hemolytic factors in the serum.<sup>60</sup> Similar to immune hemolytic reactions requiring complement, PNH acid hemolysis is inhibited by small increases in ionic strength and is favored by conditions of low ionic strength. The reaction also requires Mg<sup>++</sup>, but, unlike classic immune hemolytic reactions, is independent of Ca<sup>++</sup>.<sup>87</sup> Co<sup>++</sup> and Mn<sup>++</sup> are the only divalent cations that can substitute for Mg<sup>++</sup><sup>60</sup>; high concentrations of Ca<sup>++</sup> will actually inhibit the reaction.<sup>58,87,138</sup>

The phenomenon of increased susceptibility of PNH cells to hemolysis by *immune mechanisms* has been used for the detection of serum antibodies not demonstrable by other means.<sup>21</sup> This increased sensitivity to antibody-mediated lysis appears to be due to an increased sensitivity to complement rather than an increased reactivity with antibody; since agglutinin titers are the same for PNH and normal cells,<sup>79</sup> approximately the same amount of antibody is bound by both types of cells<sup>60</sup> and the same amount of complement is fixed by normal and PNH cells equally sensitized by antibody.<sup>118</sup>

It has been postulated that the increased sensitivity of PNH cells to complement is related to a *structural defect of the cell membrane*, but the true nature of the defect remains elusive. Certain changes have been revealed by *electron microscopy*<sup>21,80,134</sup> and include a patchy, pitted red cell surface and many cleft-like faults (Fig. 29-2), but it has not been established that these changes reflect the primary corpuscular defect.

The most consistently demonstrated *biochemical abnormality* of PNH erythrocytes is a decrease in membrane acetylcholinesterase (AChE) activity.<sup>27,49,72,93</sup> The deficiency is a regular finding in severe and moderately severe cases<sup>95</sup> and is most pronounced in cells

Fig 29-2 A and B Scanning electron micrographs (X11 000) of red cells from patients with PNH. Note protruberances, craters, and pits at site of cell concavity. C and D, Transmission electron micrographs (X10,000) of (C) normal red cell membrane and of (D) PNH like cell (AET treated cell) showing loss of membrane structure. Compare with Figure 3-11 page 94 (From Lewis et al,<sup>41</sup> courtesy of the authors and the Journal of Clinical Pathology)

that are most susceptible to hemolysis *in vivo*.<sup>72</sup> Normally, AChE activity is highest in young erythrocytes and decreases progressively with age, but young PNH cells appear to be as deficient in this enzyme as older cells. Nevertheless, it is unlikely that low AChE levels are directly responsible for the lysis of PNH cells, including reticulocytes,

since inhibition of enzyme activity in normal cells *in vitro* does not lead to increased acid hemolysis,<sup>72</sup> and *in vivo* inhibition of AChE does not influence the red cell survival time.<sup>96</sup> In addition, the enzyme appears to be absent from the red cells of several animal species and this has no apparent ill effect.<sup>47</sup> Since reduced AChE activity accompanies other

insults to red cells such as treatment with proteolytic enzymes,<sup>105</sup> anti-red cell sera,<sup>12</sup> hyperbaric oxygen,<sup>89</sup> or reduced glutathione,<sup>4</sup> it seems likely that reduced AChE activity is a secondary rather than a primary abnormality.

The lipids of the red cell have also received wide attention, but there is no agreement as to whether an abnormality actually exists. Reported changes include a decrease of phosphatidyl choline and an increase in phosphatidyl serine<sup>16</sup>; a decrease in both arachidonic and linoleic acid content<sup>83</sup>; an increase in arachidonic and pentanoic acid and a decrease in the oleic acid content.<sup>87,98</sup> Still other studies report no quantitative differences in phospholipid and fatty acid composition.<sup>76,107</sup> Dietary intake is known to bring about changes in red cell lipids (Chapter 3, page 98) and it is not clear whether adequate dietary controls were adhered to during the reported studies.<sup>76</sup> Nevertheless, there is no doubt that PNH red cells exposed to  $H_2O_2$  form more lipid peroxides and are more readily lysed by  $H_2O_2$  than are normal cells,<sup>91</sup> even though cellular glutathione peroxidase and catalase activities are normal<sup>90</sup> and there is no apparent tocopherol deficiency in PNH. In addition, lipids extracted from PNH erythrocytes are more than normally susceptible to peroxidation by ultraviolet light.<sup>91,94</sup> It has been suggested that PNH red cells may suffer from some basic abnormality of lipid structure which renders them susceptible to excessive peroxidation and membrane damage.<sup>91</sup> Others consider the lipid changes to be secondary to a more fundamental defect.<sup>92</sup>

On the basis of studies in which a PNH-like defect was induced by incubating erythrocytes in alkaline solutions of reduced glutathione (GSH),<sup>4,124,128</sup> some workers have postulated that the primary biochemical lesion of PNH cells may consist of altered SS-SH configurations close to the surface of the cell.<sup>92</sup> To such changes has been attributed the unusual behavior of PNH cells with respect to complement, as well as the lipid abnormalities.<sup>92</sup>

There appears to be no clinically significant abnormality of glycolysis.<sup>7</sup> In addition,

cellular levels of reduced glutathione fall within the normal range and remain stable under stress.<sup>7,90,125</sup> A decreased rate of  $^{32}P$  uptake and release has been reported in the face of a more rapid breakdown of ATP,<sup>157</sup> but these changes are poorly understood and probably do not contribute significantly to the pathophysiology of the PNH erythrocyte.

PNH granulocytes and platelets appear to share the membrane defect of PNH red cells since they also are much more sensitive to lysis by complement or antibodies than are normal cells.<sup>2,35</sup> This observation has led to the suggestion that PNH is the result of a somatic mutation in the primitive stem cell<sup>2</sup> (Chapter 2). The frequent association with aplastic anemia (page 959) suggests that the types of stem cell injury that result in aplasia may, under some circumstances, induce the somatic mutation leading to PNH.

### Clinical Manifestations

Usually PNH begins insidiously. The course tends to be prolonged and constant in any given individual. The diagnosis is made most frequently in the third and fourth decades of life, but occasionally PNH is encountered in childhood<sup>21,25,108,113</sup> or in old age.<sup>21,25</sup> Both males and females are affected. There is no familial tendency and the disease has been described in many racial groups.<sup>25</sup> The illness may range in severity from a mild, clinically benign defect to a chronically debilitating and lethal process.

Most commonly, patients initially complain of weakness, yellowish discoloration of the skin, and other symptoms of chronic hemolysis without obvious hemoglobinuria (Table 29-1). Because PNH is frequently not considered in such patients, the proper diagnosis is often delayed; in one study the average time interval between the onset of symptoms and the correct diagnosis was two and one-half to three years.<sup>21</sup>

The classic presentation of hemoglobinuria or discolored urine is present initially in only a quarter of all patients, and many of these do not suffer from nocturnal exacerbations. Nocturnal hemoglobinuria, when present,

Table 29-1. Presenting Features in 80 Patients with PNH\*

Signs and Symptoms	Number of Patients
Symptoms of anemia	28
Hemoglobinuria	21
Hemorrhagic signs or symptoms	14
Aplastic anemia	10
Gastrointestinal symptoms	8
Hemolytic anemia with jaundice	7
Iron-deficiency anemia	5
Thrombosis or embolism	5
Infections	4
Neurologic signs or symptoms	3

\*From Dacie and Lewis<sup>21</sup> courtesy of the authors and *Series Haematologica*

occurs as the result of an increase in hemolysis during sleep. It is not due to night time per se, since the rhythm can be reversed if the patient stays awake at night and sleeps by day.<sup>22,40</sup> In patients suffering from nocturnal hemoglobinuria, the urine is usually darkly discolored in the morning and clears during the day. However, when hemolysis is intense, hemoglobinuria may persist throughout the day.

The cause of the *nocturnal exacerbation* is poorly understood. Retention of CO<sub>2</sub> with a slight fall in plasma pH has been a popular explanation,<sup>21,39</sup> but avoidance of CO<sub>2</sub> retention by the use of a Drinker respirator failed to prevent the nocturnal sleep rhythm of hemoglobinuria.<sup>14</sup> However, the exacerbation of hemolysis that has been noted to follow strenuous exercise<sup>6,130</sup> is associated with a small reduction in the pH of the blood<sup>6</sup> and it is likely that acidity is even more pronounced in organs with slow blood flow or stasis, thereby providing a suitable environment for increased destruction of PNH erythrocytes.<sup>47</sup> It has also been postulated that nocturnal hemolysis is related to the circadian rhythm in cortisol excretion<sup>43</sup> but this has been questioned by others.<sup>25</sup> Prednisone (30 to 40 mg) does not suppress sleep-related hemolysis in all patients.<sup>43</sup>

In addition to the sleep-related rhythmicity

in hemolysis and hemoglobinuria, most patients suffer from irregularly recurring *exacerbations in hemolysis*, the cause of which is usually unclear. Sometimes exacerbations are precipitated by infections, even minor ones<sup>40,85</sup>; menstruation<sup>21</sup>; transfusions<sup>18,21,40,42</sup>; operations<sup>21</sup>; the taking of iron salts<sup>21,119</sup>; or vaccinations.<sup>122</sup> The attacks of hemoglobinuria are unrelated to cold exposure.

Mild hemolytic episodes often pass without significant symptoms, but more severe attacks may be characterized by substernal, lumbar, or abdominal pain together with drowsiness, general malaise, fever, and headaches. The abdominal pain may be colicky and may last for one or two days. The abdomen may be tender to examination, especially in the left upper quadrant, with guarding and increased symptoms on rebound. The back pain resembles that noted in patients with other types of intravascular hemolysis (Chapters 13 and 27). It is maximal in the lumbar region. Headaches may be severe and sometimes last for several days.

The most serious *complications* include marrow aplasia, thromboses, and infections. The association between *aplastic anemia* and PNH<sup>24,78</sup> has been documented in at least three distinct circumstances: in familial aplastic anemia (Fanconi's),<sup>23</sup> in aplastic anemia likely to have been of drug origin,<sup>24,86,110,121,123,133</sup> and in cases of unknown etiology.<sup>78,132</sup> Indeed, many patients have been followed for prolonged periods with a diagnosis of aplastic anemia and, since they have had few of the obvious changes usually associated with hemolytic disease, the diagnosis of PNH has not been made until the appropriate tests on the patient's red cells (see below) were carried out. In one series of 80 patients, aplastic anemia was the first diagnosis in 23 cases.<sup>25</sup> Less commonly the diagnosis of hemolysis is made first and pancytopenia develops subsequently.<sup>25</sup>

PNH is associated with a striking *predisposition to intravascular thromboses*<sup>106</sup> especially within the venous circulation. These account for about 50% of all deaths in patients with PNH. Fatal thromboses usually

involve the portal system,<sup>14,106</sup> or the brain,<sup>67</sup> but thromboses are also common in the extremities or elsewhere.<sup>106,122,136</sup>

*Abdominal pain* (see above) should always be considered secondary to intra-abdominal thrombosis until proven otherwise. Thrombosis may occur within the portal or mesenteric veins, but progressive, diffuse *hepatic venous thrombosis* (HVT) appears to be particularly common and usually runs a rapidly fatal course,<sup>106</sup> most patients dying within a few months of the onset of this complication. The clinical manifestations include, in addition to abdominal pain, nausea, a sudden increase in liver size (though HVT may occur in the absence of hepatomegaly), and, late in the disease, ascites, often of sudden onset.<sup>106</sup> Serial isotope scans and angiographic studies of the liver may be of help in the diagnosis of HVT<sup>106</sup>; enzymes such as LDH and SGPT usually become elevated, but other tests of liver function appear to be of limited value.<sup>106</sup>

Severe and refractory *headaches* (see above) may be due to small-vessel thromboses or they may be premonitory signs of progressive cerebrovascular thrombosis.<sup>106</sup> Isotopic brain scans and electroencephalograms, however, are usually of little help in monitoring PNH patients with headaches.<sup>106</sup>

The liberation of thromboplastic material from hemolyzed red cells may be responsible for the increased tendency to thrombosis that characterizes PNH.<sup>88,100,106</sup> Others have postulated that intravascular coagulation may be triggered by the interaction of complement components with complement-sensitive PNH platelets,<sup>106</sup> or that vascular occlusion may be caused by stroma derived from broken-down red cells.<sup>106</sup>

*Infections* occur frequently and may be partially attributable to leukopenia or, perhaps, to functional defects of leukocytes. The latter include defective granulocyte migration, decreased stickiness to filters, defective phagocytosis, and increased lysis in acidified serum and in the presence of antibodies.<sup>35</sup> In one series of 53 deaths, five were attributed to infection,<sup>13</sup> but even mild infections may constitute a serious hazard, since they may

precipitate an exacerbation of the hemolytic process,<sup>30,81</sup> or may lead to aplastic or aregenerative crises, which carry the same serious prognosis as in other hemolytic anemias.<sup>102</sup> Occasionally PNH has terminated in *acute myeloblastic leukemia*<sup>61,65,71,123</sup> and has been reported to occur in association with myelofibrosis<sup>45,71</sup> (Chapter 57) or erythroleukemia<sup>10</sup> (Chapter 47).

*Physical examination* may reveal background pallor and a superimposed jaundice or bronze discoloration of the skin. Moderate splenomegaly is usual, and mild to moderate hepatomegaly is sometimes found. The association of splenomegaly with aplastic anemia (see below) is often a clue to the real nature of the disease. Physical examination is otherwise unrevealing.

### Laboratory Findings

**BLOOD.** In most patients *anemia* is severe, the hemoglobin often being less than 6 g/dl. The red cells are usually macrocytic, but there may be considerable variation in their size.<sup>112</sup> Occasionally, when urinary iron loss has been considerable (see below), the red cells may appear hypochromic and microcytic.<sup>39,111,119</sup> Spherocytes and other abnormal red cell shapes are not seen, but occasional red cell fragments have been described.<sup>102</sup> When present, they may indicate a complicating intravascular thrombosis. In addition to polychromatophilia, *normoblasts may be found. There may be a marked relative reticulocytosis*, but the absolute reticulocyte count is often inappropriately low in relation to the severity of the anemia. The osmotic and mechanical fragility of the erythrocytes is normal,<sup>18</sup> and the reaction to the direct Coombs' test is negative.<sup>21</sup>

*Leukopenia* is often detected and may be marked. There may or may not be neutropenia and relative lymphocytosis.<sup>49</sup> The neutrophil alkaline phosphatase often is very low or absent<sup>77</sup> and the leukocyte acetylcholinesterase (AChE) also has been found to be low.<sup>113</sup> Functional leukocyte defects have been demonstrated<sup>75</sup> (see above). *Thrombocytopenia* of moderate degree is common, but

platelet life span and function generally are normal,<sup>33</sup> although membrane defects leading to increased susceptibility of platelets to destruction by complement components have been described.<sup>2,35</sup>

**PLASMA.** The plasma may be golden brown, reflecting the presence of increased levels of unconjugated bilirubin, hemoglobin, and methemalbumin. Predictably, serum haptoglobins are very low and lactate dehydrogenase levels may be very high during periods of active hemolysis.<sup>47</sup>

**URINE.** When there is increased blood destruction, the urine contains increased amounts of urobilinogen. In addition, intravascular hemolysis leads to depletion of serum haptoglobin and this results in the continuous presence of hemoglobin in the glomerular filtrate in the kidney (Chapter 5, page 207; Chapter 20, page 729). Much of the hemoglobin is reabsorbed by the cells of the proximal convoluted tubules, which become heavily laden with iron. The excretion of this iron in the form of granules gives rise to hemosiderinuria.<sup>53</sup> The urinary sediment is tobacco-yellow in color and gives a positive iron reaction in the Prussian blue stain. Brown granules of altered blood pigment may be seen in the leukocytes or epithelial cells, or outside the cells. In addition, spectroscopic examination may reveal the presence of varying amounts of free hemoglobin.

The *hemosiderin* can be demonstrated as follows: 15 ml of urine are centrifuged in a graduated 15-ml centrifuge tube. The supernatant solution is drawn off down to the 1-ml mark and discarded. The sediment is suspended in the supernatant solution and to this is added an equal volume of 5% hydrochloric acid. After mixing, 0.5 ml of a 10% aqueous solution of potassium ferrocyanide is added. This is mixed and a drop is examined microscopically. When the reaction is positive, blue granules of hemosiderin will be seen, especially within the cells.

A permanent preparation can be made by smearing the urinary deposit on a glass slide and allowing this to dry in air, after which it is fixed by dipping the slide in methyl

alcohol for 10 to 20 minutes. It is then stained for 10 minutes in freshly prepared acid-potassium ferrocyanide solution that is kept at 56° C in a water bath. The slide is washed in running water for 20 minutes, rinsed in distilled water, and finally counterstained with 0.1% safranin or eosin.

The continuous loss of relatively large amounts of iron in the urine may produce *iron deficiency*.<sup>135</sup> Average daily excretions of up to 15.9 mg have been observed<sup>21</sup> and as much as 3.6 mg in 24 hours have been demonstrated even in the absence of hemoglobinuria.<sup>8</sup> It is noteworthy that, despite the continuous presence of hemoglobinuria, *renal function* usually is not seriously affected<sup>120</sup> unless there is some unrelated complicating factor. Albumin has been detected immediately before and after an episode of hemoglobinuria,<sup>14</sup> but usually no protein can be demonstrated between attacks.

**BONE MARROW.** Normoblastic hyperplasia is the characteristic finding. As many as 50% of the nucleated cells may be normoblasts<sup>122</sup>; only occasionally are megaloblastic changes seen.<sup>135</sup> The number of megakaryocytes may be decreased. When there is pancytopenia, a hypoplastic marrow may be found, although in many patients pancytopenia is associated with a cellular marrow.<sup>85</sup>

**SPECIFIC SEROLOGIC TESTS.** The diagnosis of PNH is based on a series of special tests that exploit the sensitivity of PNH red cells to lysis by small amounts of complement.<sup>63</sup>

The susceptibility of PNH erythrocytes to lysis in acidified human serum forms the basis of the *Ham test*.<sup>40</sup> The optimum pH for this reaction is between 6.5 and 7.0. The patient's serum should not be used for the test since it may have been depleted of complement and other heat-labile serum factors.<sup>5</sup> Instead, ABO compatible normal serum, obtained by defibrination of the blood in an open flask, preferably from a donor known to have potent serum,<sup>127</sup> is used. The serum is acidified by adding one volume of 0.2N HCl to nine volumes of serum.<sup>19</sup> Nine volumes of acidified serum are in turn added to one volume of a 50% suspension of washed red corpuscles

obtained from the patient. Frank hemolysis is seen with PNH erythrocytes but may also occur with those from patients suffering from hereditary dyserythropoietic anemia (HEMPAS, page 700) or from spherocytosis, either hereditary or acquired, since spherocytes are easily hemolyzed at hydrogen ion concentrations that leave normal cells intact. The hemolytic property of HEMPAS cells differs from that of PNH cells in that not all normal sera produce acid hemolysis of HEMPAS cells, hemolysis does not occur in the patient's own serum, and reaction to the sucrose hemolysis test (see below) is negative.<sup>63</sup> In order to exclude the possibility of acid hemolysis due to spherocytosis or antibodies, two controls are included in the test system<sup>20</sup>: (1) patient's corpuscles suspended in acidified heat-inactivated serum; and (2) normal corpuscles suspended in the patient's acidified serum. Both will yield negative results in patients with PNH. A third control test may be made by adding the patient's corpuscles to normal serum. Little or no hemolysis will take place if the patient has PNH, whereas hemolysis may occur if immune hemolysins are present. In the latter situation the reaction to Coombs' test, which is negative in PNH patients, will also be positive. Heat inactivation does not, of course, prevent acid hemolysis of spherocytes.

The *thrombin (Crosby) test* is simpler but probably less specific than the Ham test.<sup>20,59</sup> It depends on the increase in hemolysis that occurs when bovine thrombin is added to an acidified cell-serum suspension.<sup>16</sup> Hemolysis is attributed to the presence of heterophil hemolytic antibody contaminating the bovine thrombin preparations, but some enhancement may also occur as the result of other contaminating proteins such as complement components.<sup>63</sup>

The excessive hemolysis of PNH erythrocytes in solutions of low ionic strength containing small amounts of normal serum forms the basis of the so-called *sugar water test*<sup>51</sup> and the *sucrose water test*.<sup>44,54,64</sup> Isotonic solutions of other simple sugars or sugar alcohols will have the same effect, provided the compound selected does not permeate the red

cells.<sup>66</sup> Since all red cells become coated with complement components during incubation in these solutions, it is thought that the positive reaction ultimately depends on the increased sensitivity of PNH red cells to lysis by complement. In these solutions, complement appears to be activated by antigen-antibody-like reactions<sup>51</sup> or in the alternate pathway C3A activator system<sup>37</sup> (see also page 325). A *screening test*<sup>54</sup> consists of adding one part of citrated or oxalated blood to nine parts of freshly prepared sugar water (10 ml of commercial sugar dissolved in distilled water to a final volume of 100 ml). The red cell suspension is gently mixed and incubated for 30 minutes at room temperature. The red cells are then sedimented by centrifugation and the supernate is inspected for gross hemolysis. If no hemolysis is present, the patient probably does not have PNH, provided he has not had recent massive transfusions. A more refined and confirmatory sucrose hemolysis test has been detailed elsewhere.<sup>54,63</sup> It should be stressed that heparin or EDTA are unsuitable as anticoagulants for this test; they frequently lead to false negative results. Defibrinated blood should also not be used, since false positive hemolysis may occur in disorders other than PNH.<sup>54</sup>

The *heat test* is a useful and simple screening procedure.<sup>56</sup> Two to 3 ml of blood are clotted in a glass test tube and allowed to incubate at 37° C from one to three hours. The clot is then removed, and the remaining contents of the test tube are centrifuged. In PNH, the supernatant serum is bright red. The test also yields a positive result in the presence of spherocytes and certain anti-red cell antibodies, but a negative result is strong evidence against the diagnosis of PNH.<sup>63</sup>

*Hemolytic antibody tests* are based on the observation that PNH cells are lysed by smaller quantities of anti-red cell antibodies than are normal cells.<sup>21,117</sup> These tests generally utilize the cold agglutinin, anti-I, and the need for such specific antibodies constitutes the major disadvantage of the test. In addition, the sensitivity of the system has to be adjusted in such a way that PNH erythrocytes are hemolysed, while other cells are not.<sup>63</sup>

## Differential Diagnosis

The diagnosis of PNH must be considered in any patient who has (1) signs of intravascular hemolysis of undefined cause, especially in the presence of hemoglobinuria; (2) pancytopenia in association with hemolysis, whether the marrow is cellular or not; (3) persistent, poorly explained iron deficiency, especially when accompanied by hemolysis; (4) evidence of recurrent venous thrombosis, especially intra-abdominally; and (5) unexplained recurrent bouts of abdominal pain, low backache, or headache in the presence of chronic hemolysis. PNH must be differentiated from antibody-mediated hemolytic anemias, especially paroxysmal cold hemoglobinuria (page 925) and the cold agglutinin syndrome (page 921), and from HEMPAS (page 700).

## Treatment

No definitive therapy is available and management is complicated by a highly variable clinical picture. Some patients have only a moderate degree of anemia, with little hemoglobinuria, and in such patients "he prescribes best who prescribes least."<sup>13</sup> Others have severe anemia punctuated by hemolytic crises, thromboses, and infection; in such patients treatment is necessary but is often unsatisfactory.

*Blood transfusions are valuable in the therapy of anemia, but must be given in the form of saline-washed red cells<sup>18</sup> since fresh donor plasma may accelerate the hemolytic process by supplying labile factors essential for hemolysis. Presumably these factors are consumptively depleted in individuals suffering from chronic hemolysis. Others have attributed febrile and even hemolytic transfusion reactions to the presence of leukoagglutinins<sup>52</sup> and have used leuko-filtered blood in some patients. Normal cells survive well in patients with PNH, and transfusion to nearly normal hemoglobin levels has been observed to produce short-lived remissions.<sup>18,49</sup> This may be due to a temporary decrease in the production of abnormal cells, with a consequent reduction of hemolytic and other phenomena.*

Sooner or later iron deficiency develops in most patients<sup>52,135</sup>, sometimes even though repeated transfusions have been administered. The iron loss must be replaced. Most patients tolerate oral iron therapy well,<sup>50</sup> but accelerated disease activity has been observed in many,<sup>53</sup> and has also been reported following administration of iron-dextran.<sup>60</sup> This phenomenon has been attributed to cell damage caused by iron-catalyzed peroxidation of erythrocyte lipids<sup>60</sup> but more probably results from the outpouring of young erythrocytes, which may be more "sensitive" than the older antecedent population. It has been suggested that iron can be given without major complications if reticulocytosis is first suppressed by transfusions, but this hypothesis requires confirmation.<sup>62</sup>

*Steroids usually are not helpful<sup>31,69</sup> but may be useful in a few patients,<sup>31,52</sup> some of whom have had a positive reaction to the antiglobulin test,<sup>31</sup> a rare occurrence in PNH. It has been suggested that steroids be tried in patients unresponsive to other measures and in females of childbearing age.<sup>52</sup> High doses (40 mg prednisone daily) should be given for at least two weeks before a patient is considered unresponsive. If the patient does respond, maintenance doses of 5 to 10 mg should be employed.<sup>52</sup>*

*Androgen therapy may possibly be of some benefit.<sup>50,52,53</sup> Fluoxymesterone in large starting doses (60 mg daily) and in maintenance doses of 10 to 30 mg daily has been employed. This may result in elevated hemoglobin levels or decreased transfusion requirements.<sup>52</sup> The improvement appears to be accounted for by decreased hemolysis rather than increased erythropoiesis, even though the basic cellular defect is unchanged.<sup>52</sup>*

*Anticoagulants have been advocated for two purposes: (1) to reduce the amount of hemolysis and (2) to prevent or treat thromboses. Because heparin does block the hemolysis of PNH cells in vitro,<sup>52</sup> some believe that it may also reduce hemoglobinuria when given to patients<sup>71</sup>; others have been unable to demonstrate any benefit,<sup>52,73</sup> and some claim that severe hemolytic reactions*

may even be precipitated by heparin.<sup>13,32</sup> It is likely that hemolysis is not influenced one way or another.<sup>52</sup> The use of coumadin and related compounds has also given varied but generally disappointing results<sup>15,21,52,60,101</sup> and is not currently recommended for the treatment of chronic hemolysis.

Anticoagulation probably does have a place in the treatment and prevention of venous thromboses.<sup>15,52,104</sup> Since thromboses are particularly common following surgical procedures and in the puerperium<sup>52</sup> it has been suggested that, in these situations, patients be anticoagulated at the first sign of intravascular thrombosis. Heparin has also been advocated as the agent of choice in the treatment of the patient having progressive, diffuse hepatic vein thrombosis (HVT). Although it has afforded temporary relief, it has failed to halt the inexorably downhill course.<sup>106</sup> Coumadin has proved equally inadequate in protecting against the recurrence of clinically obvious HVT.<sup>100</sup>

*Dextran* (molecular weight 72,000 or preferably 142,000) has been shown to inhibit PNH hemolytic tests in vitro<sup>21,34,36</sup> and has been used for the temporary control of hemolysis associated with infection, trauma, and transfusion reactions.<sup>31,36,129</sup> But its long-term use is dangerous because hemorrhagic complications, antibody formation, and anaphylactic reactions will likely develop. Generally 0.5 to 1.0 l of a 6% solution is sufficient to decrease temporarily the rate of hemolysis. *Dextran's mode of action* is unknown. Penicillamine,<sup>30</sup> tocopherols, 6-mercaptopurine, and a number of other drugs<sup>52</sup> have been tried without success.

*Splenectomy* has provided no permanent benefit and has been followed by death in some instances.<sup>122</sup> A few patients have been reported to have less frequent episodes of hemoglobinuria after splenectomy than prior to it,<sup>21,40</sup> but this may have been coincidental.

In one patient with PNH and marrow failure, the successful transplantation of marrow from a histocompatible sibling resulted in restoration of marrow cellularity and normal hematopoietic function.<sup>128</sup>

## Course and Prognosis

PNH is a chronic disease, the median survival being approximately 10 years.<sup>25</sup> Some patients have survived for 20 years or longer after diagnosis, and one for 43 years.<sup>11,25</sup> The severity of the disease is reflected in the degree of anemia, which in turn is a function of the proportion of complement-sensitive cells and the degree of marrow aplasia. Complications are less predictable. Thromboembolism, a major cause of death, is particularly associated with increased hemolysis, whereas hemorrhage and infection are the most common causes of death in patients suffering from marrow aplasia.<sup>25</sup>

In some PNH patients the severity of the illness lessens with time and a small number achieve a complete clinical remission.<sup>23</sup> Some patients in clinical remission retain laboratory abnormalities for years,<sup>11</sup> whereas others lose all laboratory signs of PNH.<sup>25</sup>

#### Course, Complications, and Prognosis

## General Considerations

### Definitions and Terminology

The term "polycythemia," which means "many cells," is used commonly to refer to an increase in red blood corpuscles, without any implication regarding the number of leukocytes or platelets. However, an increase in the concentration of red corpuscles, whether measured as number of cells, hemoglobin, or packed cell volume, is more correctly designated as *erythrocytosis*. The contrasting condition, *erythremia*, in which the numbers of leukocytes and platelets usually are increased

also, is a disorder of the hemopoietic system. It is more commonly called *polycythemia rubra vera* or *polycythemia vera* (PV).

### Relative and Absolute Erythrocytosis

Erythrocytosis may or may not be associated with an increase in the total quantity of red cells in the body, ie, an increase in red cell mass. *Relative (or pseudo) erythrocytosis* occurs when, through a loss of blood plasma, the concentration of red corpuscles becomes greater than normal; the total number in the circulating blood is not increased. Such events are usually of brief duration (page 975). *Absolute erythrocytosis* refers to a true increase in the total number (mass) of circulating red cells. A rapid, *transient erythrocytosis* may develop in some species of animals when red corpuscles are shunted into the circulation from the splenic storage pool, but this does not occur in normal man (Chapter 8). Absolute erythrocytosis in man is chronic and results from a sustained increase in red cell production. Since red cell survival in erythrocytosis and in polycythemia vera usually is normal, modest increases in erythrocyte production lead to proportionate increases in red cell mass. Furthermore, as red cell mass increases above normal levels, total blood volume also increases (Fig. 30-1), although this occurs somewhat unpredictably because of variable changes in plasma volume.<sup>18</sup>

Fig 30-1 The relationship of red cell mass to total blood volume in persons with normal, and increased red cell volume (From Huber et al,<sup>18</sup> courtesy of the author the British Journal of Haematology)

#### Clinical Manifestations and Pathologic Physiology

The clinical manifestations of erythrocytosis are partly related to the underlying disorder. In addition, the increased blood volume and increased blood viscosity that occur in erythrocytosis and in polycythemia vera in themselves produce certain symptoms and signs. These are related to the degree of the increase and the resulting effects on blood flow and oxygen transport. Thus, the "ruddy cyanosis" seen in patients with polycythemia vera is a consequence of the expanded blood volume and resulting dilatation of cutaneous vessels, coupled with the somewhat sluggish flow therein, which, in turn, is caused by the increased blood viscosity.<sup>13</sup> The "black cardiac" (page 980) has a similarly expanded blood volume and vascular system, but, in addition, suffers from a lack of adequate oxygenation of the circulating hemoglobin. Headache, dizziness, tinnitus, a full feeling in the head, and a tendency to bleeding and/or thrombosis may develop in patients with erythrocytosis and an enlarged blood volume regardless of the basic cause.<sup>25</sup> These symptoms usually are relieved by phlebotomy.

#### Blood Viscosity, Blood Volume, and Blood Flow, and Oxygen

It has been difficult to achieve understanding of the clinical of erythrocytosis because of technical limitations. Neither blood volume nor blood viscosity is easily measured (The most accurate measurement of blood viscosity in man were made by allowing blood to flow through an 18-gauge mm diameter) under a mean pressure of 200 to 400 mm saline) and rate.<sup>30</sup> The blood viscosity was calculated on the basis of Poiseuille's law, in part, that the resistance to flow in capillaries is proportional to the length of the capillary (raised to the fourth power), which is valid for Newtonian fluids, but which does not change with time but is not strictly applicable to non-Newtonian fluids such as blood. The resulting data showed that under conditions of study, blood viscosity increased rapidly with increasing packed cell volume (Fig. 30-2). However, the data do not apply to rigid tubes and

Fig 30-2. The relationship between the absolute viscosity of whole blood and the VPRC is shown in the upper curve (Modified from Pirofsky<sup>30</sup>). In the lower curve, relative flow through a capillary tube of fixed diameter and length and propelled by a fixed pressure gradient is calculated for blood with different VPRCs and thus different viscosity (Modified from Castle and Jandt<sup>10</sup>).

of about 6 ml per minute. At higher flow rates (higher rate of shear) the entire curve would shift downward and to the right (page 124, Fig. 3-25), reflecting a decrease in viscosity.<sup>40</sup> Furthermore, viscosimetry measurements made in capillary tubes yield values that probably are higher than those that occur physiologically.<sup>40</sup> It also is of interest that, at constant values for volume of packed red cells (VPRC), blood viscosity increases as the red cell size decreases. Thus goat and camel erythrocyte suspensions were more viscous than those of humans or dogs.<sup>34</sup>

From blood viscosity values at different

packed cell volumes (Fig. 30-2) it is possible to calculate the rate of blood flow through a tube under a given set of conditions (again somewhat misusing Poiseuille's law).<sup>10</sup> Such calculated values are shown in the lower portion of Figure 30-2 in which it is apparent that, as VPRC and viscosity increase, the calculated flow rate through a capillary of fixed diameter decreases linearly. From these values for blood flow at different values for VPRC and the oxygen content of such bloods, one can calculate the rate of oxygen transport. The result is an inverted arc-like curve as shown in Figure 30-3A which illus-

trates that bloods of different cell content flowing through a capillary tube under a fixed pressure would deliver rather different amounts of oxygen.<sup>10</sup> Very similar curves were obtained for normovolemic dogs (Fig. 30-3B, dashed curve) when the measured

cardiac output and the VPRC values were used to calculate the approximate oxygen transport at different packed red cell volumes.<sup>27,31</sup> In both curves, oxygen transport was low at low VPRC values because of low blood oxygen content (left side of Fig.

Fig 30-3 Arterial oxygen transport at different VPRCs and thus different viscosity values. A, The values in this curve were calculated from the blood viscosity values as measured by Pirofsky<sup>30</sup> and the flow values calculated in the lower portion of Figure 30-2 B Systemic oxygen transport as calculated from cardiac output measured in normovolemic and hypervolemic dogs (From Murray et al,<sup>27</sup> courtesy of the authors and the *Journal of Clinical Investigation*)

30-3). At high VPRC levels (right side of Fig. 30-3), calculated oxygen transport also is low in spite of high oxygen content because the increase in viscosity results in slowed blood flow. At intermediate levels, calculated oxygen transport is considerably higher and appears to be optimal at about normal hematocrit values.<sup>4,10,27,31</sup> That such an optimum VPRC level for maximal oxygen transport was found in experimental animals with normal blood volumes (Fig. 30-3B) suggests that the calculated values (Fig. 30-3A) may have physiologic significance.<sup>4,27,31</sup> In particular, these observations may explain the effect of anemia in causing tissue hypoxia<sup>5</sup> and increased erythropoietin production.

At elevated VPRC values these same curves predict low oxygen transport and tissue hypoxia, as already mentioned; as a result, increased erythropoietin production would be expected and this should lead to increased numbers of red cells. However, this prediction is not in accord with several observations, namely, the adequate tissue oxygenation<sup>9,36,42</sup> and normal erythropoietin<sup>1,15</sup> values found in hypertransfused animals and in patients with polycythemia vera, as well as the fact that hypertransfusion results in a decrease in erythropoiesis<sup>2,15,42</sup> rather than increasing tissue hypoxia, thereby leading to a vicious cycle of increasing red cell production. The explanation for this apparent paradox may lie in the fact that, as the red cell mass increases, the blood volume does not remain constant; instead, the blood volume expands as the red cell mass expands (Fig. 30-1). One effect of increasing the blood volume is to increase cardiac output, mainly by increasing stroke volume.<sup>12,27</sup> Thus, in acutely hypervolemic dogs, the cardiac output was about twice that of normovolemic dogs with similar VPRC values.<sup>27</sup> Peripheral vascular resistance (PVR) increased also as packed cell volume was increased, but PVR was less in hypervolemic animals than in those with normal blood volumes at similar values for VPRC.<sup>27</sup> The oxygen transport curve in acutely hypervolemic dogs<sup>27</sup> and rodents<sup>38</sup> showed an inverted arc configuration similar to that seen in normovolemic animals

(Fig. 30-3B), but oxygen transport levels were elevated and the maximum value was shifted to the right.<sup>36</sup>

Measurements of cardiac output and calculated oxygen transport in man have yielded somewhat different results.<sup>12</sup> The mean cardiac output in 10 patients with polycythemia vera (mean VPRC 0.60 l/l) was 4.8 l/min/m<sup>2</sup> as compared to 3.65 l/min/m<sup>2</sup> in six normal controls (Fig. 30-4). In contrast, anemic patients showed a marked decrease in oxygen transport in spite of a twofold increase in cardiac output (Fig. 30-4)<sup>8</sup>; in other words, in anemia the increased cardiac output does not fully compensate for the decreased blood oxygen content.<sup>10</sup> When oxygen transport was calculated from these data<sup>10</sup> a divergence from the inverted arc configuration was noted (Fig. 30-4, dashed line). However, it must be noted that in the patients with polycythemia vera the total blood volume presumably was increased (Fig. 30-1), while in the normal and anemic subjects it was not.

The probable situation with respect to oxygen transport in persons with erythrocytosis or polycythemia vera as compared to normal and anemic subjects is illustrated in Figure 30-5. In absolute erythrocytosis and in polycythemia vera, because of the associated hypervolemia, the oxygen transport curve is similar to that in normovolemic states but it is elevated and shifted to the right.<sup>27,36</sup> Thus, in compensated hypoxic states, polycythemia is beneficial because it leads to hypervolemia and increased oxygen transport (compare points 1 and 2 in Fig. 30-5). In patients with absolute erythrocytosis or polycythemia vera, oxygen transport may be increased, normal, or decreased as compared to the normovolemic state (Fig. 30-5, points 3, 4, and 5 respectively), depending on the degree of polycythemia and the resulting changes in viscosity and blood flow.

**RELATION TO TREATMENT OF POLYCYTHEMIA.** The foregoing considerations are of interest in understanding not only the pathophysiology of erythrocytosis and polycythemia vera but also the treatment thereof. In polycythemia vera there is little or no general

Fig 30-4 Curve A The relative oxygen transport *in vitro* by blood with various values for VPRC (the same curve as in Fig 30-3A) Curve B, Oxygen transport in man derived from measured values obtained in 10 patients with polycythemia vera [cardiac output (CO)  $1\frac{1}{2} \times$  normal] 6 normal subjects [CO 3.65 l/min/m<sup>2</sup>]<sup>12</sup> and in anemic patients [CO  $2 \times$  normal] (From Castle and Jandl<sup>10</sup> courtesy of the authors and Henry M Stratton, Inc.)

need for increased tissue oxygen transport. However, in some local areas where fixed vessel diameter (from arteriosclerosis) limits increased blood flow the additional impeding effect of increased blood viscosity may limit oxygen transport and result in local tissue ischemia; the local vessel changes may interfere with the ability of increased blood volume and resulting increased cardiac output to compensate for the greater viscosity effects at high hematocrit levels. Because of this, when treating by phlebotomy, it is best not to reduce the blood volume too greatly at any one bleeding, especially in patients with known arteriosclerotic symptoms (angina pectoris, transient ischemic attacks, etc.). Rather, time should be allowed for hemodilution to occur between phlebotomies, or in emergencies the blood volume may be maintained by infusing saline or plasma expanders<sup>16</sup> or by reinfusing the removed plasma.<sup>475</sup> Obviously, in such patients a sudden fall in blood volume from other causes, such as dehydration or acute hemorrhage, may also

result in local ischemia because the high viscosity effects cannot be compensated for by increased cardiac output. In patients with congestive heart failure, the need for reduction of blood viscosity may be urgent since the ability to increase cardiac output in order to compensate for the increased blood viscosity has been compromised. The oxygen hemoglobin dissociation curve is shifted to the right in such patients.<sup>22</sup>

In hypoxemic erythrocytosis, blood oxygen transport is less efficient at comparable hemoglobin or VPRC levels than in polycythemia vera because of arterial oxygen unsaturation. Therefore, the curves for oxygen transport would be lower than in situations in which hemoglobin oxygenation is normal (Fig. 30-5). In the presence of decreased arterial oxygen saturation, tissue hypoxia may persist even when there is marked erythrocytosis. The main advantage to be derived from decreasing blood viscosity and blood volume in hypoxic (secondary) erythrocytosis is to decrease the cardiac work

Fig 30-5 Hypothesis depicting the relationship between oxygen transport and VPRC in normovolemic and hypervolemic situations. Cardiac output is assumed to remain constant. Point 1 refers to a normal subject at rest, with normal VPRC and normal oxygen transport. Point 2 describes the patient with erythrocytosis (elevated VPRC, blood volume and oxygen transport) at rest. Points 3, 4 and 5 refer to the effects of increasing VPRC; oxygen transport presumably decreases from optimal values as the VPRC increases, but may exceed values for oxygen transport in normovolemic patients until very high VPRC values are reached. Point 5 indicates the situation in normovolemic polycythemia produced by exchange transfusion, i.e., increased VPRC, decreased oxygen transport. (Modified from Thorling and Erslev<sup>36</sup> courtesy of the authors and Henry M. Stratton, Inc.)

load. From the curves in Figure 30-5, one would predict that in such situations an increase in tissue oxygen transport should result from phlebotomy. However, the variable and unpredictable results of phlebotomy observed in patients with hypoxia-induced erythrocytosis<sup>21</sup> indicate that factors other than blood viscosity and oxygen transport may be involved. Better results have been reported when exchange transfusion with dextran was used to maintain blood volume.<sup>16</sup> In helping to achieve the best balance between increased cardiac work and decreased tissue hypoxia in patients with hypoxemic erythrocytosis the subjective feelings of the patient probably are the best guides.<sup>10</sup>

### Classification<sup>24</sup>

As stated earlier, erythrocytosis must be distinguished from polycythemia vera; furthermore, in patients in whom hematocrit or hemoglobin levels are found to be increased, it is necessary to determine whether the erythrocytosis is relative or absolute. The various forms of absolute erythrocytosis are listed in Table 30-1. These and polycythemia vera can be differentiated from relative erythrocytosis on clinical grounds, as will be described below, and also, when necessary, by measurements of blood volume. The latter, however, are not easily interpreted. Normal values are presented in Table 30-2, but there

**Table 30-1. Classification of Polycythemia**

---

I	Erythrocytosis
A.	Relative erythrocytosis (pseudoe erythrocytosis)
1	Hemoconcentration burns, shock, acute ascent to high altitude, diarrhea prolonged sweating
2	Stress erythrocytosis (Gaisböck's syndrome, ?normal variant)
B.	Absolute erythrocytosis
1	Secondary to decreased tissue oxygenation (anoxic erythrocytosis)

is considerable variation from one subject to another in red cell, plasma, and total blood volume, even when expressed as ml/kg body weight. This variation results, in part, from differences in body fat content<sup>19,20,28,41</sup>; thus, blood volume is more closely related to lean body mass<sup>28</sup> than to weight or surface area.

It is a common practice to measure either plasma volume or red cell volume, and, from one of these determinations, total blood volume is calculated on the basis of the relative amounts as indicated by a hematocrit determination. In the view of most<sup>6,7,38</sup> but not all<sup>34</sup> investigators, this practice increases the chance of error. It is better to measure red cell mass and plasma volume separately.

It should be emphasized that blood volume measurements do not differentiate between absolute erythrocytosis and polycythemia vera, and thus they are useful only in distin-

guishing absolute from relative erythrocytosis.

The classification presented in Table 30-1 is based on pathophysiologic as well as clinical grounds. It is now recognized that red cell production at the erythroblast level may be stimulated by erythropoietin. Decreased tissue oxygenation, no matter what the cause, leads to increased production of erythropoietin (Chapter 4), but this hormone may also be elaborated "inappropriately," as in certain tumors, renal cysts, and the like. It has also been found that hematopoiesis, beginning at the stem cell level, may increase autonomously, with only partial regulation by the usual homeostatic mechanisms of oxygen tension and erythropoietin; the latter phenomenon occurs in polycythemia vera.<sup>1,32</sup> On theoretical grounds, it might be expected that measurement of serum or urine erythropoietin levels would be useful in differentiating the various forms of polycythemia. This has not yet proved to be the case. First of all, high serum levels of erythropoietin are not usually found in patients who are responding to endogenous erythropoietin; rather, elevated serum levels are found in the sera of patients with faults in erythropoiesis, as in aplastic anemia.<sup>38</sup> Furthermore, values even for urinary excretion of erythropoietin over a few hours<sup>75</sup> have varied widely.<sup>1,2</sup> Most important of all is the fact that methods for measurement of erythropoietin that are both accurate and sensitive, and are also widely available, have not yet been described.

## Relative Erythrocytosis

### Transient Erythrocytosis

Lowered fluid intake, marked loss of body fluids, or a combination of both will cause a decrease in plasma volume and relative erythrocytosis. This decrease in plasma volume occurs when there is persistent vomiting, severe diarrhea, especially with copious sweating, and postoperatively,<sup>57,66</sup> and also soon after an individual reaches a high altitude.<sup>61</sup> A less obvious cause is an increase in

\*RBC volume measured by <sup>51</sup>Cr method. Other values calculated without correction for trapped plasma.

†These are the only values of which we are aware at altitudes significantly above sea level. They may be somewhat low for unknown reasons since the packed cell volumes at 1600 meters were the same as at sea level, a finding in contradiction with our own large experience.

insensible fluid loss, as occurs in fever, hyperthyroidism, or diabetic acidosis. By other mechanisms, loss of electrolytes from the extracellular compartment without concomitant loss of body water leads to a decline in osmolar concentration in the extracellular fluid. The resulting shift of water into the tissue cells may produce relative polycythemia, sometimes of high grade.<sup>57</sup> In burns, loss of plasma leads to hemoconcentration. Also, in certain types of circulatory failure there may be a loss of plasma into the interstitial spaces; such a shift takes place largely in the capillary beds with the result that erythrocytosis may be more marked there than in the central blood vessels.<sup>57</sup> In most of these situations the cause of the hemoconcentration is apparent from the history and examination of the patient, and the process is of brief duration, lasting only a few hours to several days.

#### Chronic Forms

These have been variously referred to as Gaisbock's syndrome,<sup>53</sup> "stress" erythrocyto-

sis,<sup>60</sup> benign polycythemia,<sup>64</sup> benign erythrocytosis,<sup>64</sup> spurious polycythemia,<sup>50</sup> or pseudopolycythemia.<sup>58</sup> In one large series of 215 patients referred with a diagnosis of polycythemia vera,<sup>62</sup> 18 were thought to have chronic relative erythrocytosis, and it was postulated that this might be caused by stress.<sup>60</sup> These patients were predominantly males with an average age of 43 years (16 to 68), and thus many were younger than patients who have polycythemia vera. Many were mildly obese; also many had hypertension. In 6 of the patients the volume of packed red cells was in the high normal range, while in 12 the values were greater than 0.50 l/l. The leukocyte counts were normal ( $< 11.0 \times 10^9/l$ ). Although 11 had "ruddy cyanosis," none had a palpable spleen. The red cell volume was normal, but the plasma volume was subnormal. Follow-up for 6 to 24 months, during which time no treatment was given, revealed no change in clinical symptoms or laboratory findings.<sup>60</sup> Similar groups of patients have been described in other reports.<sup>54,58,66</sup> In one study<sup>66</sup> the VPRC was found to be greater than three

standard deviations above the normal mean in 18 of 25 patients, ranging up to 0.65 1/1. However, total red cell volume, determined in 10 of the subjects, was increased in only 3 of this group. In retrospect, perhaps the 3 patients suffered from true erythrocytosis secondary to some obscure cause such as an abnormal hemoglobin (page 982); the other 7 apparently had relative erythrocytosis.

It is doubted that stress erythrocytosis and Gaisböck's syndrome are true clinical entities.<sup>50,52</sup> The view that an arbitrary value for volume of packed red cells should be considered as the upper limits of normal has no statistical foundation. The values generally accepted as normal at sea level, or at any given altitude, represent the mean  $\pm 2$  standard deviations. This indicates that, on the basis of the normal frequency distribution curve for this physiologic parameter, the values in 2.3% of the population lie above this range. Such "odd men out"<sup>52</sup> should not be regarded as necessarily being abnormal. Also the evidence that hypertension or stress is a pathogenetic factor is tenuous.<sup>52</sup> Attempts to produce stress erythrocytosis in rats were unsuccessful.<sup>56</sup>

Many individuals with relative erythrocytosis unfortunately have had venesections and have even been treated with radioactive phosphorus. That phlebotomy is neither called for nor justified is indicated by the fact that it has not proved useful in alleviating symptoms such as dizziness, in contrast to the relief of these symptoms in polycythemia vera afforded by this means.<sup>62,66</sup> The differential diagnosis of these conditions and polycythemia vera is discussed on page 995.

## Absolute Erythrocytosis

An absolute increase in red cell mass may result from a variety of causes but also is the chief manifestation of the hemopoietic disorder, polycythemia vera.

### Anoxic Erythrocytosis

Insufficient oxygen supply to the tissues may come about as a result of: (1) decreased

atmospheric oxygen pressure, eg, high altitude; (2) pulmonary diffusion or mixing abnormalities; (3) right-to-left cardiopulmonary shunts as in congenital heart disease; (4) hypoventilation; or (5) impaired oxygen-carrying capacity of hemoglobin. In all of these disorders the deficient supply of oxygen in the tissues is presumably detected by some sensing organ(s), possibly in the kidney, and this in turn leads to the production of erythropoietin and an increase in red cell mass (page 180, Chapter 4).

### At High Altitudes

In 1890, Viault<sup>95</sup> showed that erythrocytosis develops during sojourn at high altitude. He found erythrocyte counts of  $7.5$  to  $8.0 \times 10^{12}$  cells/l not only in natives living in the Peruvian Andes and working in a mine at an altitude of 4,392 m above sea level, but in himself and in a fellow traveler as well, although his blood count in Lima (160 m) had been normal. In a Himalayan expedition it was demonstrated that red cell volume and total hemoglobin rose progressively as higher altitudes were attained and at 19,000 feet (5800 m) reached mean values 49% above those at sea level. The increase in total blood volume was partially masked by reductions in plasma volume.<sup>89</sup> Similar responses to rarified atmospheres have been observed in animals.<sup>98</sup>

The rapid ascent to high altitude is accompanied by symptoms of fatigue, dizziness, pulsating headache, anorexia, nausea, vomiting, insomnia, and irritability, a syndrome well known to mountain climbers and residents of high altitudes and referred to as acute mountain sickness.<sup>78,84,92</sup> The symptoms first appear some 4 to 6 hours after reaching a high altitude, but may be delayed for up to 96 hours, suggesting that the pathogenesis may be more complex than simple hypoxia. The incidence and severity of these symptoms are related to the altitude achieved and the susceptibility of the individual. Thus, all persons will develop symptoms if suddenly transported from sea level to 15,000 feet (4,570 m) or higher, while a few develop

symptoms at 8 to 10 thousand feet (2400 to 3000 m).<sup>78</sup> After 4 to 8 days, acclimatization usually occurs and symptoms remit spontaneously.<sup>92</sup> In some individuals, however, symptoms may progress to cerebral confusion, coma, and even death due to pulmonary edema<sup>92</sup> unless the subject is returned to low altitude.<sup>77</sup> The pathogenesis of acute mountain sickness is thought to involve hypoxia and subsequent excessive secretion of anti-diuretic hormone and adrenal steroids with resulting fluid retention, increased blood volume, and finally cerebral edema and/or pulmonary congestion.<sup>92</sup> The incidence and severity of symptoms can be considerably reduced by administering diuretics such as acetazolamide or furosemide.<sup>90,92</sup>

The events that are associated with acclimatization after arrival at high altitude are not understood completely but probably include: (1) An increase in erythrocyte 2,3-DPG levels<sup>83</sup> and a shift to the right in the oxygen-hemoglobin dissociation curve,<sup>77,82,87</sup> thus allowing better tissue delivery of oxygen in spite of decreased arterial oxygen saturation (Fig. 3-16). The increase in 2,3-DPG appears to more than compensate for the left shift in the curve that results from the initial hypocapnia and increase in arterial pH.<sup>77,92</sup> (2) An increase in plasma and urinary erythropoietin<sup>96</sup> levels with subsequent increase in plasma iron turnover, reticulocytosis,<sup>75</sup> and increase in red cell mass and blood volume. (3) Subsidence of the initial excessive anti-diuretic hormone and adrenal steroid secretion and return to the normal diurnal variation of plasma steroid levels.<sup>92</sup> The final result is a new equilibrium at decreased oxygen saturation and carbon dioxide tension with increases in alveolar ventilation, respiratory frequency, and red cell mass.<sup>77,78</sup> These manifestations of acclimatization are quickly lost on descent to sea level even after many years of residence at high altitude.

In some well-acclimated individuals, after a few or many years of good adaptation to high altitude, excessive erythrocytosis (beyond the expected altitude response) is noted. This progresses to hematocrit values approaching 0.80 l/l, and often an incapac-

itating illness characterized by alveolar hypoventilation develops. This entity is known as *chronic mountain sickness* or *Monge's disease*.<sup>78,85</sup>

Monge<sup>84</sup> described an "emphysematous type" and an "erythremic type." In the *emphysematous* form the dominant symptom is dyspnea and there is a long history of bronchitis and laryngitis. Cyanosis is present. The thorax is globular and the vital capacity is diminished. The *erythremic* type, when mild, is characterized by some diminution in mental and physical fitness, fatigue, an erythremic color that turns to cyanosis on the least exertion, occipital headache, anorexia that increases as the day goes on, nausea, vomiting, diminution of visual acuity, and paresthesias. In other instances, headache, dizziness, tinnitus, vague pains in the extremities, cough, and hemoptysis occur. When the disorder is more severe, there is incessant dyspnea, aphroia is common, and there is profound lethargy and even coma. Crises of mental confusion have been observed. Sexual coldness is common. Not only may paresthesias be present but also excruciating pain may be felt in the lower extremities. The face is bluish-violet, the eyelids are edematous and bluish, the sclerae are intensely colored by distended capillaries, the tongue is thick, the hands are enlarged and turgid, and the fingers are clubbed. Hypotension is often present. The liver and spleen have been found to be enlarged only in about 10% of the subjects.

Erythrocytosis is characteristic and is more marked than in other residents of the same altitude who have no symptoms. Counts of  $7.0 \times 10^{12}/l$  are common and  $9.06 \times 10^{12}$  cells/l were found in one of Monge's patients.<sup>84</sup> There is a corresponding, sometimes a slightly greater, rise in hemoglobin and volume of packed red cells.<sup>94</sup> MCV is normal or slightly increased and MCHC is normal.<sup>80,94</sup> Reticulocytes may be increased,<sup>80,84</sup> although in most instances they are normal. The leukocyte count often is normal,<sup>80</sup> although Monge described slight leukocytosis together with monocytosis. Hyperbilirubinemia may be pronounced, and is due mainly to unconjugated bilirubin. There is greater

blood destruction, as measured by fecal urobilinogen, than in normal residents of high altitudes.<sup>83</sup> Remarkable increases in blood volume have been recorded, as great as 212 ml/kg body weight, with 173 ml for red cell volume and 28 to 43 ml/kg for plasma volume.<sup>80</sup> More recent, and probably more accurate, determinations have indicated a less striking although still greatly increased red cell volume (88 to 95 ml/kg body weight).<sup>83</sup> Although platelet counts have been found to be normal or high, clot retraction is poor. Epistaxis is common and hemoptysis, bleeding of the gums, and purpura may occur.

Those affected usually are in the fourth to sixth decade of life. Remissions and relapses are described. Ascent to still higher altitudes results in aggravation of the symptoms, whereas descent to sea level relieves them. Cardiac impairment does not appear until late and death has occurred more often from hemorrhage, pulmonary tuberculosis, or bronchopneumonia than from cardiac insufficiency.

The decreased oxygen saturation of the arterial blood in individuals residing at high altitudes is not correlated with the development of symptoms of chronic mountain sickness. In natives with chronic mountain sickness the arterial  $p\text{CO}_2$  is higher than in their own native control group.<sup>85</sup> In residents of high altitudes it appears that the several forms of chronic mountain sickness reflect the development of one or another of the types of chronic lung disease also seen in persons residing at sea level. It is plausible to assume that intrinsic pulmonary disease, too mild to cause signs or symptoms at sea level, is the cause of Monge's disease in many instances. This was the finding in a patient observed in the Rocky Mountains of the United States.<sup>79</sup> The erythremic type may be due to inappropriately low ventilatory response, secondary to reduced respiratory sensitivity to  $\text{CO}_2$ ,<sup>85</sup> and thus may be similar to some hypoventilation syndromes seen at sea level (page 981). There is, in fact, considerable clinical similarity between Ayerza's disease (page 980) and chronic mountain sickness. A person afflicted with the former

disease, however, could probably not live at altitudes of 10,000 feet (3000 m) or higher.

Differential diagnosis should not be difficult. Cases of congenital heart disease can be distinguished by the cardiac findings. In acquired heart disease, cyanosis is associated with signs of cardiac failure, whereas such signs are lacking when cyanosis is present in Monge's disease. The chief distinction from polycythemia vera is the failure of polycythemia to be altered by increased oxygen pressure. In Monge's disease, descent to sea level brings about complete relief of symptoms, together with a pronounced reduction in the blood volume and restoration of normal blood counts.<sup>80</sup>

### Pulmonary Disease

A variety of diseases, such as chronic obstructive lung disease, diffuse pulmonary infiltrates (fibrous or granulomatous), kyphoscoliosis, and multiple pulmonary emboli, lead to erythrocytosis as the result of inadequate oxygenation of the blood circulating through the lungs. However, not all patients with lung disease and decreased arterial oxygen saturation have elevated hemoglobin or hematocrit levels<sup>118,120</sup> and only in about 50% is there an increase in red cell volume.<sup>127</sup> The reason for this suboptimal response to tissue anoxia is not clear, but it does not appear to result from a decrease in erythropoietin production or the presence of chronic infection.<sup>118,120,127</sup> When erythrocytosis occurs it is usually associated with an increased MCV, reduced MCHC,<sup>130</sup> and a normal MCH.<sup>118</sup> Although it has been suggested that iron deficiency may be a factor in these changes in corpuscular indices,<sup>112</sup> there is little evidence to support this. More plausibly the red cell changes have been attributed to swelling, which in turn may be due to carbon dioxide retention.<sup>118</sup> It has been suggested that carbon dioxide retention may inhibit the marrow response, but no evidence is available to support this.<sup>118</sup> If erythrocytosis is present it can be reduced by continuous oxygen administration.<sup>111</sup>

*Cavernous hemangiomas of the lung may*

be associated with erythrocytosis.<sup>132</sup> *Pulmonary arteriovenous fistula* should be suspected when a peculiar murmur in a lung field together with abnormal roentgenographic shadows (Fig. 30-6) are associated with erythrocytosis, cyanosis, and other symptoms suggesting pulmonary disorder, such as hemoptysis and clubbing of the fingers.<sup>124,126,133</sup>

#### *Chronic Cor Pulmonale*<sup>114</sup>

The clinical picture of this syndrome varies, but oxygen deficiency with arterial desaturation and elevated pulmonary artery pressure are of central importance.<sup>114,122</sup> The erythrocytosis with its associated increase in blood viscosity, increased blood volume, and tendency to thrombosis appears to be the physiologic price of a compensatory mechanism progressively stretched beyond its ameliorating capabilities to the point at which it is more injurious than beneficial.<sup>115</sup> As

already mentioned, phlebotomy may at times be helpful in relieving symptoms, but this is unpredictable (page 974). As in less severe pulmonary disease the MCV of the red cells tends to be increased above normal,<sup>110</sup> whereas MCHC generally is lower than normal.<sup>121</sup>

#### *Ayerza's Syndrome*

This syndrome, characterized clinically by slowly developing asthma, bronchitis, dyspnea, and cyanosis with associated polycythemia, was described by Ayerza in 1901. Congestive failure may be present and there is usually evidence of dilatation and hypertrophy of the right ventricle. Such patients have been referred to as black cardiacs (*cardiacos negros*).<sup>125,129</sup> The essential pathologic change is primary disease of the pulmonary artery or its branches.<sup>131</sup> This has been attributed to syphilis,<sup>133</sup> but more often there is pulmonary arterial and arteriolar sclerosis.<sup>134</sup>

Fig 30-6 Pulmonary arteriovenous fistula associated with polycythemia

In some cases, congenital narrowing or hypoplasia of the pulmonary artery may play a role. The spleen is sometimes enlarged, clubbing of the fingers is present, and chronic heart failure and passive congestion of the liver eventually occur.

### Congenital Heart Disease

Red cell counts of  $7.0$  to  $8.5 \times 10^{12}/l$  are common in persons with congenital heart disease and there are reports of counts as high as  $10.0$  and  $13.9 \times 10^{12}/l$ .<sup>145</sup> The volume of packed red cells was as high as  $0.86$  l/l blood in one of our patients. Erythrocytosis occurs in patients in whom there is a partial shunt of the blood from the pulmonary circuit. The most common defects producing such erythrocytosis are pulmonary stenosis (usually with defective ventricular or atrial septum, patent forameo ovale, or patent ductus arteriosus), persistent truncus arteriosus, complete transposition of the great vessels, and the tetralogy of Fallot (pulmonary stenosis, defective ventricular septum, dextroposition of the aorta, right ventricular hypertrophy). Individuals with such defects exhibit evidence of disturbed cardiorespiratory function, marked cyanosis, clubbing of the fingers and toes, and sometimes stunted growth. It has been reported that an enlarged spleen is not uncommon, but in our experience we have not found this to be the case.

The total plasma volume may be reduced below normal, but the increase in the size of the red cell mass is so great that the total blood volume usually is higher than normal.<sup>141,146</sup> The fatty tissue in the bone marrow is replaced by hematopoietic marrow.<sup>145,148,149</sup>

In a series of 41 subjects<sup>144</sup> the serum bilirubin and the serum iron were found to be increased above normal, but no higher than would be expected from the total increase in hemoglobin metabolism as represented by the erythrocytosis.

It is generally assumed that the underlying stimulus to the hematopoietic system is low oxygen tension resulting from shunting of unoxygenated blood through or around the

lungs with consequent unsaturation of the arterial blood. The arterial oxygen saturation often is as low as 30 to 35%. With successful operative intervention this may rise to 75 and even 88% and, with this, the erythrocytosis disappears. The effect of the anoxia, however, is not a direct one on the bone marrow but is mediated by humoral factors concerned in the regulation of bone marrow activity, as discussed in Chapter 4 (page 180).

### Acquired Heart Disease

In acquired heart disease such erythrocytosis as may develop is of minor degree and is correlated to some extent with the degree of decompensation. The erythrocytosis has been reported as being accompanied by evidence of intensified erythropoiesis in the bone marrow, an increase in red cell mass, and some macrocytosis.<sup>140</sup>

### Hypoventilation Syndromes

Erythrocytosis is found occasionally in patients who exhibit no evidence of pulmonary disease or cardiovascular shunts. Such patients may erroneously be considered as having Gaisbock's syndrome (page 976).<sup>169</sup> The primary defect in at least some of them appears to be an inadequate ventilatory drive from the respiratory center in the brain.<sup>114,163</sup> Such a defect has been found in patients suffering from the *Pickwickian syndrome*, so-called because of the clinical picture of the fat boy described in Dickens' *Pickwick Papers*.<sup>160</sup> In association with extreme obesity, these patients exhibit somnolence, cyanosis, and hypercapnia and may develop periodic respiration, ultimately with right ventricular failure. Voluntary hyperventilation alleviates the hypercapnia, and in many but not all patients, loss of weight restores alveolar ventilation to normal and reverses the syndrome.<sup>113</sup> However, not all massively obese individuals develop alveolar hypoventilation and erythrocytosis. It appears that it is only in the presence of an insensitive respiratory center that a massive panniculus limits respiratory function and results in alveolar

hypoventilation, hypoxemia, and hypercapnia.<sup>161</sup> In some patients the decreased ventilatory drive is of unknown cause,<sup>167</sup> perhaps congenital, or due to idiopathic disease of the medullary respiratory center ("Ondine's curse"<sup>163</sup>), whereas in others it may have resulted from bulbar poliomyelitis, vascular thrombosis, or previous encephalitis.<sup>114,161</sup> In any case, the consequent hypoxemia results in elevated levels of erythropoietin and erythrocytosis, with packed cell volumes as high as 0.75 l/l.<sup>163</sup>

### Abnormal Hemoglobins<sup>220</sup>

Hereditary abnormalities in the hemoglobin molecule and possibly acquired changes in the oxygen-binding capabilities of hemoglobin are among the rarer causes of erythrocytosis.

#### *Hereditary Abnormalities of Hemoglobin*

At least 23 genetic abnormalities in the amino acid sequence of the hemoglobin molecule that result in increased affinity of the hemoglobin molecule for oxygen have been recognized. Of these, six (hemoglobins Köln, Freiburg, H, G<sub>Georgia</sub>, Rampa, and Tacoma) are in various degrees unstable (Chapter 24), and either normal blood values or anemia has been observed rather than erythrocytosis. Erythrocytosis was not reported in association with hemoglobin Denmark Hill,<sup>219</sup> which affects the same structural site as Hb G<sub>Georgia</sub> and Hb Rampa. In Hb Abruzzo<sup>218</sup> the substitution affects the same site as Hb Little Rock, but the hematologic effects, if any, have not been reported. The remaining 15 (Table 30-3) are associated with mild to moderate erythrocytosis. White blood cell and platelet counts have been normal. It seems likely that, in the past, in some individuals with such hemoglobins the diagnosis of familial polycythemia, benign erythrocytosis, or even Gaisböck's syndrome has been made. With the exception of an apparent increase in stillbirths and abortions in some women with hemoglobin Yakima,<sup>202</sup> no significant untoward effects have been observed

and no treatment is indicated. Abnormal maternal-fetal oxygen exchange could explain the fetal mortality.

Inheritance has been autosomal dominant. In the largest families studied,<sup>182,190</sup> as many as 20 individuals in four generations were affected. Most of the abnormal hemoglobins discovered so far have been demonstrable by starch gel electrophoresis in tris-EDTA-borate buffer at pH 8.6, but hemoglobins Rainier<sup>180</sup> and Bethesda<sup>188</sup> required agar gel electrophoresis at pH 6.2. Abnormal electrophoretic behavior and even chromatography, however, cannot be relied upon to reveal all hemoglobin abnormalities (Chapter 24). In the last analysis, altered oxygen affinity of the blood, as measured by the partial pressure of oxygen at which hemoglobin is half saturated ( $P_{50}$ ), must be measured. For example, in Hb Olympia,<sup>217</sup> a battery of electrophoretic and chromatographic methods failed to demonstrate a hemoglobin abnormality. It was the reduced  $P_{50}$  that revealed the increased oxygen affinity of the blood. By appropriately excluding an alteration in the intracellular content of diphosphoglycerate (DPG), the one other type of abnormality that can cause altered oxygen affinity, an abnormal hemoglobin remained as the only explanation of the abnormal red cell function. Appropriate studies then revealed the nature of the amino acid substitution in Hb Olympia.

The normal effect of pH on oxygen affinity (Bohr effect) (Chapter 3) is reduced by a number of these mutations; this tends to shift the oxygen hemoglobin dissociation curve to the left. In addition, in the great majority of these mutations, impaired interaction between the four hemoglobin subunits ("heme-heme" interaction) was present. This effect is indicated by a change in the oxygen dissociation curve to a more hyperbolic and less sigmoid shape (Fig. 30-7). The physiologic effect of these changes is to impair the release of oxygen in the tissues. How this functional impairment is produced has been the subject of interesting studies of the effects of the amino acid substitutions on the quaternary structure of hemoglobin (Chapter 4). The location of all but three of the substi-

tutions has been either in a position that could interfere with  $\alpha_1\beta_2$  contacts or at the carboxy terminal end of the  $\beta$ -chain (Fig. 30-8). It has been postulated that the equilibrium between oxyhemoglobin and deoxyhemoglobin may be altered to favor the oxy-form if: (1) the mutation introduces a bigger side chain that is a misfit in the deoxy-form; (2) a concentration of groups of equal charge results that repel each other in the deoxy-forms; (3) the amino acid substitution leads to the loss of a hydrogen bond stabilizing one or the other of the two quaternary structures; or (4) there is impairment of the binding of 2,3-DPG in deoxyhemoglobin. The last is the situation with Hb Little Rock.<sup>187,213</sup>

As illustrated in Figure 4-17 (page 177), it has been shown that normally, on oxygenation, the contact area at the  $\alpha_1\beta_2$  interface shifts from one dovetailed position to another. Eight of the abnormal hemoglobins associated with increased oxygen affinity involved this interface (Table 30-3). In Hb Yakima<sup>202,210</sup> and in Kempsey,<sup>215</sup> replacement of aspartate G1 $\beta$  may cause an intra-chain shift in the normal relations between the F and G helices and the heme group, or the substituted side chain may disturb the region of contact between nonpolar residues of the  $\alpha$ - and  $\beta$ -chains in a way to favor the oxy structure.

With reference to substitutions at the carboxy terminal (Fig. 30-8), Perutz has shown

Fig 30-8 The approximate structure of the  $\alpha$ - and  $\beta$ -chains of hemoglobin showing the positions of known substitutions leading to increased oxygen affinity and secondary erythrocytosis

that the position of the penultimate tyrosine changes on oxygenation (Chapter 4). In Hb Bethesda,<sup>188</sup> the substitution of histidine for the penultimate tyrosine of the  $\beta$ -chains may prevent adequate stabilization of the deoxy tetramer; the partially ionized histidine is unable to occupy the hydrophobic pocket and, as a consequence, formation of the oxygen-linked salt bridges of the  $\beta$ -carboxy terminal histidine may be prevented. In Hb Rainier,<sup>189,205</sup> the penultimate  $\beta$ 145 cysteine residues may form intramolecular disulfide bonds with the  $\beta$ 93 cysteine residues and these may change the conformation around the tyrosine residues with resulting alteration in the  $\alpha\beta$  contact. Perutz suggests that replacement of histidines H 21(143) by aspartates would generate a pair of competing negative charges that would bind the imidazoles of histidines HC 3(146)  $\beta$  in both the oxy and deoxy forms, thus keeping their pKs permanently high and inhibiting their contribution to the Bohr effect.<sup>212</sup>

Whether or not erythrocytosis develops depends on a number of factors, eg, (1) the

proportion of abnormal hemoglobin; (2) interaction between normal and abnormal hemoglobins in the heterozygous state during binding with oxygen; (3) reactivity of the abnormal hemoglobin with organic phosphates present in erythrocytes, such as 2,3-DPG; (4) the magnitude of change in oxygen affinity of the hemoglobin; and (5) the stability of the hemoglobin. It is possible also that, in certain instances, the influence of other factors, such as blood loss, had not been ruled out as an explanation for lower hemoglobin levels than would otherwise have been expected.

Erythropoietin levels in patients with this type of hemoglobinopathy usually are not increased. This can be readily explained, however, if one assumes that a new homeostatic equilibrium has been achieved; at the time of study, the tissue anoxia has already stimulated erythropoietin production, and this in turn has induced erythrocytosis. When such patients were bled to normal hematocrit levels, reticulocytosis occurred and increased erythropoietin excretion developed;

as these individuals returned to their usual, compensated state of erythrocytosis, erythropoietin excretion dropped to normal.<sup>180</sup>

Cyanosis rather than erythrocytosis is characteristic of patients with hereditary methemoglobinemia<sup>236</sup> due to enzymatic defects that result in decreased reduction of methemoglobin (Chapter 31). Mild compensatory erythrocytosis may occur but this is inconstant. Likewise, in the Hb M disorders (page 1015), erythrocytosis is rare even in those due to substitution in the  $\beta$ -chain in which increased oxygen affinity has been observed. The absence of erythrocytosis may be explained by the fact that these variants are somewhat unstable.

### Acquired Abnormalities of Hemoglobin

A number of drugs and chemicals, such as nitrites, nitrates, aniline derivatives, sulfonamides, and various amines and nitrobenzene types of compounds, will produce toxic levels of methemoglobin and/or sulfhemoglobin in the blood of even normal persons.<sup>231,234,238</sup> Individuals with defects in methemoglobin reduction are especially sensitive to such agents<sup>232,236</sup> (Chapter 31). To our knowledge, clear erythrocytosis has not been demonstrated in patients with toxic methemoglobinemia. However, an increase in hemoglobin above pretreatment levels was seen in patients with sickle cell anemia given paraminopropiophenone in doses sufficient to maintain a methemoglobin level of between 20 to 30%.<sup>230</sup> Occasionally, in heavy smokers, carboxyhemoglobin concentration may reach sufficiently high levels (4 to 6.8%) to produce absolute erythrocytosis.<sup>239</sup> In phosphorus poisoning, especially in persons working in the match industry, polycythemia was described,<sup>240</sup> but this may have been merely relative erythrocytosis resulting from acute liver damage.

### Tumors and Miscellaneous Disorders<sup>270</sup>

Erythrocytosis has been described in association with a variety of neoplasms, cysts, and vascular abnormalities (Table 30-4).

**Table 30-4. Reports of Erythrocytosis Associated with Tumors and Cysts<sup>270</sup>**

	Number of Cases
<b>Adrenal and renal disorders</b>	
Hypernephroma	118
Cystic kidney disease	35
Hydronephrosis	14
Hepatocellular carcinoma	63
Cerebellar hemangioblastoma	50
Leiomyosarcoma of uterus	23
<b>Rarely (1 to 5 case reports)</b>	
Renal adenoma, hemangioma, sarcoma, ischemia, and renal artery stenosis	
Pheochromocytoma	
Hepatic hamartoma	
Wilms' tumor	
Myxoma of the atrium <sup>241</sup>	
Carcinoma (gastric, bronchogenic, prostatic, ovarian)	

### Hypernephroma and Renal Disorders<sup>270</sup>

Erythrocytosis has been reported in association with hypernephroma in 118 patients and it is estimated that 1 to 4% of patients with hypernephroma may develop erythrocytosis.<sup>270</sup> Erythrocytosis also has been reported in occasional patients with renal carcinoma, sarcoma, hemangioma, adenoma and Wilms' tumor,<sup>270</sup> renal cysts, hydronephrosis, or polycystic kidneys,<sup>233,254,258,270</sup> and, in one patient with renal ischemia due to disease of the extrarenal vasculature.<sup>261</sup> In a number of subjects a true increase in red cell mass was demonstrated. The rate of plasma iron disappearance was rapid and plasma iron turnover was increased, as in polycythemia vera.<sup>254</sup> When the lesions were removed the erythrocytosis disappeared. Extracts of the removed tumor or cyst were found to have erythropoietic activity in a number of instances, and when the tumors recurred erythrocytosis reappeared. However, in other patients with erythrocytosis no increase in erythropoietic activity could be demonstrated in the serum, cyst, or tumor. Furthermore, erythropoietic activity has been found in renal tumors or cysts removed from patients

without erythrocytosis.<sup>270</sup> Thus, in most but not all cases studied, erythropoietin or a precursor appeared to have been synthesized in the tumor or cyst or perhaps in compressed, adjacent normal tissue, and released into the circulation or concentrated in the lesion. Experiments in rabbits suggested that pressure on the renal parenchyma may cause erythrocytosis.<sup>263</sup>

### Hepatocellular Carcinoma<sup>270</sup>

Erythrocytosis also has been reported in a number of persons with hepatocellular carcinoma. An incidence of 10% was reported in one series of 176 consecutive cases.<sup>262</sup> In another series of 213 autopsied subjects whose death was due to hepatic carcinoma, in 9.4% the hemoglobin levels were above 16 g/dl, in 2.8% they were above 18 g.<sup>251</sup> Most of these liver carcinomas developed in patients with cirrhosis; consequently, splenomegaly was not unusual. Measurements of plasma volume demonstrated increased values, as is often the case in uncomplicated cirrhosis, but the red cell mass also was increased.<sup>262</sup> The rapid growth of this tumor leads to death within a few months and, as a result, few patients have been operated upon and no remission of the erythrocytosis has been reported.<sup>270</sup> An interesting case in which elevated plasma erythropoietic activity was demonstrated but no such activity could be found in the liver led to the finding of increased erythropoietin substrate in the tumor.<sup>255</sup>

### Cerebellar Vascular Tumors

About 50 cases of cerebellar vascular tumor with associated erythrocytosis have been reported.<sup>259,270</sup> Usually platelet and leukocyte concentrations were normal; the red cell mass was increased in some but not all of these patients.<sup>270</sup> The spleen was not enlarged. In several instances the presence of erythropoietic activity in tumor tissue or cyst fluid was demonstrated.<sup>250,259,270,272</sup> The removal of the tumor was associated with a return to normal hemoglobin levels in all 26 patients who were followed for a sufficient

period. Recurrence of tumor was accompanied by erythrocytosis in a few patients.<sup>270</sup>

### Leiomyoma of the Uterus<sup>270</sup>

Twenty-three cases of erythrocytosis in association with uterine myomas occurring both before and after menopause have been reported. In nearly all of these patients the tumor was large, reaching to the umbilicus or above.<sup>270</sup> In 18 of 20 patients who survived hysterectomy the erythrocytosis subsided. It is not clear whether the erythrocytosis was due to anomalous erythropoietin production,<sup>275</sup> interference with ventilation, or renal or ureteral compression caused by the large tumors, since few cases have been adequately studied.<sup>270</sup>

### Other Tumors<sup>24,270</sup>

In addition to the above, rare instances of erythrocytosis in association with a variety of other tumors have been reported (Table 30-4). From most of the case reports it is not possible to ascertain whether the erythrocytosis was relative or absolute, whether there was coincidental polycythemia vera, or whether the erythrocytosis had been caused by low arterial oxygen tension.<sup>270</sup>

It is well known that erythrocytosis with features suggesting polycythemia vera, namely, plethoric facies and leukocytosis, may be found in patients with Cushing's syndrome or primary aldosteronism.<sup>263</sup> These signs also have been observed in association with luteomas of the ovary.<sup>257</sup> Some degree of polycythemia can be produced by the administration of adrenal corticosteroids in large doses. Polycythemia has been observed in mice with masculinizing tumors (luteomas).<sup>257</sup>

### Pathogenesis of Erythrocytosis Associated with Tumors and Cysts

The erythrocytosis observed in association with tumors and other disorders discussed above has been termed *inappropriate*, in the sense that it occurs neither in response to

recognizable tissue hypoxia nor in association with a hemopoietic disorder. As indicated above, in many instances the erythrocytosis has been shown to be related to the production of erythropoietin. The erythropoietin appears to be identical with normal, physiologic, renal erythropoietin, for it is inactivated by erythropoietin antibody.<sup>273</sup> Depending on the circumstances under which the erythrocytosis has developed, a variety of mechanisms may have been responsible for the production of the erythropoietin. Knowledge in this field still is very meager. On the basis of what is known at this time, tissue anoxia induced as the result of pressure from an enlarging mass offers an acceptable explanation, but more intriguing is the implication that various tissues may be capable of producing erythropoietin or related substances under certain circumstances.

### Benign Erythrocytosis

The term "benign" or "primary erythrocytosis" was used to denote erythrocytosis not associated with leukocytosis, thrombocytosis, or splenomegaly, but characterized by increased red blood mass and total blood volume, and erythroid hyperplasia of the bone marrow, with no evidence of an underlying cause. The course was described as milder than that in polycythemia vera. It has been suggested that some patients with these findings may have a very mild form of polycythemia vera or the erythrocytosis may be due to an as yet unidentified cause; others may be at the extreme end of the normal distribution curve (page 977). The discovery of erythrocytosis associated with hemoglobins with high oxygen affinity may explain some of these cases (page 982). Other cases may have been instances of "inappropriate erythrocytosis," unrecognized as such because they were studied before it was appreciated that renal cysts and some tumors may produce erythrocytosis (page 986).

### "Benign Familial Erythrocytosis"

Scattered in medical literature are reports of families in which two or more members

had polycythemia. A review<sup>269</sup> indicated that, in addition to the dominantly transmitted hereditary forms caused by a hemoglobinopathy (page 982), there are other varieties of transmission, both dominant and recessive. The dominant forms include those in which there may be a defect in the regulation of DPG and still another variety of unknown etiologic background.<sup>269</sup>

The recessive forms have been observed in children or adolescents. In these the degree of erythrocytosis has been very striking, with hematocrit values greater than 0.71 l/l, whereas in the dominantly transmitted type, hematocrit values of 0.45 to 0.60 l/l have been found. Clinically, however, the erythrocytosis has been equally benign in both types.<sup>269</sup> Several instances of recessive familial erythrocytosis have been shown to be the consequence of a cellular defect in the regulation of production of erythropoietin or of its precursor substances.<sup>219,276</sup>

## Polycythemia Vera (Erythremia)

### Definition

Polycythemia vera is a disease of insidious onset, chronic course, and unknown cause. It is characterized by a striking, absolute increase in the number of red blood corpuscles and in the total blood volume, and usually by leukocytosis, thrombocytosis, and splenomegaly. The bone marrow is hyperplastic. The skin has a peculiar reddish-purple color and a variety of vasomotor and neurologic symptoms are manifest.

*Synonyms* include polycythemia rubra vera, splenomegalic polycythemia, Vaquez's disease, Osler's disease, polycythemia with chronic cyanosis, myelopathic polycythemia (Weber), erythrocytosis megalosplenica (Senator), and cryptogenic polycythemia (R. C. Cabot).

### History

In 1892, Vaquez<sup>240</sup> described persistent polycythemia, as distinguished from relative

and transient forms, in a man whom he took to have a congenital cardiac lesion even though there were no auscultatory signs. At autopsy, one year after the patient was first examined, his heart was found to be normal. The writings of Osler in 1903 and 1908<sup>327</sup> crystallized the clinical picture of the disease, and Türk,<sup>329</sup> in 1904, called attention to the occurrence of leukocytosis as well as to immature forms of cells of the red and white series, thus suggesting a hyperplastic disorder of blood formation. Excellent reviews of the literature have been published,<sup>21,62,311</sup> but little has been added to the clinical description since the earliest publications.

### Epidemiology

Polycythemia vera is much less frequent among Negroes than Caucasians<sup>320</sup> and is comparatively common in Jews.<sup>321</sup> Thus, in one reported series of 197 cases, in a hospital in which Negroes represented approximately 16 to 25% of all the patients,<sup>304</sup> only 7 of the patients with polycythemia vera were Negroes. Only 12 or so well-documented cases in Negroes have been reported.<sup>24,342</sup> The high incidence among Jews was first noted by Turk and is supported by the data in several series of cases.<sup>304,321,332</sup> The ratio in Jews, as compared to that in other persons, chiefly of European stock, is 2:1 or higher.<sup>320</sup> There is little to support the claim<sup>311</sup> that those affected tend to be of slender body build.<sup>304</sup>

Males are somewhat more commonly affected than females.<sup>320</sup> On the basis of a number of reports,<sup>301,320,339</sup> some of which diverge a good deal from one another, one would estimate the male to female ratio as somewhat less than 2:1, even 1.2:1.<sup>304,320</sup> The sex incidence and the age at time of diagnosis in 386 cases reported in three large series of subjects<sup>301,304,336</sup> are shown in Figure 30-9. The onset of symptoms in classic cases is in middle or later life.<sup>325</sup>

Occasional cases of idiopathic polycythemia have been reported in children.<sup>291,304,318</sup> and, of these, some were more suggestive of polycythemia vera<sup>291,318</sup> than others.<sup>304</sup> In many of these cases subsequent evaluations

indicated that most were probably cases of "benign familial erythrocytosis" (page 988).

### Pathogenesis

The symptoms and signs of polycythemia vera can be attributed in large part to the expanded blood volume and vascular space and to the slowing of the blood flow as a result of the increased viscosity of the blood.<sup>10,13</sup>

The cause of the disorder is unknown. There is no evidence that the oxygen-combining power of hemoglobin is altered nor is tissue respiration increased.<sup>311</sup> The suggestion that this disease is the compensatory result of anoxemia of the bone marrow was based on the presence of capillary thickening and subintimal and adventitial fibrosis of small vessels in the bone marrow.<sup>332</sup> However, direct measurements of bone marrow oxygen saturation gave normal values,<sup>525,527</sup> and the lack of elevated serum or urinary erythropoietin levels<sup>1,2</sup> also contradicts this hypothesis. In view of the increased production and turnover of erythrocytes, neutrophils, and platelets (page 994), and the hypercellular marrow, it appears more likely that there is abnormal cell production, perhaps beginning at the level of an uncommitted stem cell.

### Symptomatology

#### Onset

It is evident from the history in most cases that the disorder probably has been present for a long time. The presenting complaint may be headache, dizziness, ringing in the ears, or visual disturbances, or there may be dyspnea, lassitude, or weakness. Although the color of the skin is often acknowledged to have been unusual for a long time, this complaint alone rarely brings the patient to the physician. Skin and mucous membrane hemorrhages are not uncommon and these, or a sense of weight or swelling in the abdomen due to enlargement of the spleen, may be the initial symptoms. There may be such a multiplicity of symptoms that neurasthenia is

Fig 30-9 Age and sex of 386 patients with polycythemia vera.<sup>301,304,338</sup> Males are represented by hatched columns; females by dotted columns.

suspected. On the other hand there may be no complaints whatever, the polycythemia being discovered accidentally.

### Skin and Mucous Membranes

The color of the face is not like that of ordinary cyanosis but more nearly resembles that of a chronic alcoholic or that produced by blushing or exposure to a warm fire. This "rubor" may be so intense that it produces a startling appearance. The face, particularly the lips, cheeks, and tip of the nose, the ears, and the neck show this color (Fig. 30-10), but the skin of the trunk is not usually so strikingly affected. The distal portions of the extremities exhibit these changes more than the proximal portions and may be more truly cyanotic. The degree of red or blue depends upon the state of dilatation of the peripheral vascular network and upon the speed of circulation through these areas, since these factors determine the quantity of reduced hemoglobin present.<sup>318</sup> The delayed, sluggish peripheral circulation no doubt accounts for the sensitivity to cold, of which these patients may complain.

Ecchymoses of various sizes are common. In one patient, following the application of a mustard plaster, a hemorrhage that soon included almost the entire skin surface was observed<sup>345</sup>; and in another patient, ecchymosis almost as extensive followed a breast operation. Red or dark-violet spots or brownish pigmentation of the skin may be found and a great variety of skin lesions<sup>297,331</sup> have been observed (dry skin, eczema, acne-form or urticarial changes, acne rosacea, acne urticata,<sup>205</sup> urticaria pigmentosa,<sup>205</sup> and even a nodular eruption similar to the specific infiltration found in leukemia).<sup>310</sup> Purpura was observed in 8% of one series of 163 polycythemia vera patients.<sup>339</sup>

The eyes may appear bloodshot. The mucous membranes are a deep raspberry-red. Epistaxis and bleeding of the gums are common.

A common complaint is intense itching after a bath. This may be so troublesome that bathing with hot or even warm water is avoided. Less frequently, a similar reaction occurs following the use of cold water. This complaint tends to disappear as the polycythemia is treated, but returns with relapse.

Fig 30-10 Photograph of a drawing (original in color) of one of Osler's cases of polycythemia vera.

Reddening, swelling, and pain (erythromelalgia) may occur,<sup>300</sup> especially in the extremities. Club-like thickening of the terminal phalanges is uncommon.

### *Cardiovascular System*

Cardiac symptoms are not particularly prominent and cardiac hypertrophy is more frequently absent than present. The circulatory minute volume is reduced and the velocity of blood flow is greatly lowered,<sup>296</sup> but the cardiac output and work are normal.<sup>27,292</sup> The skin capillaries are distended and the capillary loops are enlarged. Vascular disease<sup>324</sup> is very common, and vascular accidents are frequent and in many instances are the cause of death. Venous thromboses occur in many of these patients and varicosities and phlebitis are often observed. Moderate or marked thickening of the peripheral arteries is found, and coronary thrombosis, claudication without occlusion, arterial occlusion with gangrene, acroparesthesia, the Raynaud syndrome, and thromboangiitis obliterans have been described.<sup>300</sup>

It has been stated that hypertension is so unusual in polycythemia vera that its presence indicates that the polycythemia is secondary in type.<sup>148</sup> This view seems extreme, for one might expect hypertension in a proportion of subjects whenever a chronic disease of middle and late life is involved. In one series of 20 patients,<sup>303</sup> systolic blood pressures greater than 140 mm Hg were found in 11 (55%) of the group. Our experience is similar (42%). In another series,<sup>315</sup> in one third of the 33% of patients in whom elevated blood pressures were present, the pressure returned to normal following successful treatment of the polycythemia.

### *Gastrointestinal System*

Besides feelings of fullness, thirst, gas pains, belching, and constipation, peptic ulcer, hemorrhage, or thrombosis may occur. Duodenal ulcer has been found in as many as 8% of patients with polycythemia vera, almost four times the number in a control

series.<sup>344</sup> In another series of 125 patients, duodenal ulcer was found in 16% and gastric ulcer in 7%.<sup>341</sup> It has been suggested that these ulcers follow thrombosis in the vessels of the first part of the duodenum and are produced by the action of the digestive juices upon the area of local necrosis.<sup>298</sup> Hemorrhage from varices in the esophagus, stomach, or bowel may be massive.<sup>293</sup>

Thrombosis in the mesenteric veins and arteries may be mistaken for peritonitis or the perforation of an ulcer.<sup>312</sup>

Enlargement of the liver is frequent (40% or more of subjects,<sup>335</sup> 50% in our series). Cirrhosis of the liver has been reported in a number of instances and some writers have distinguished, without much justification, a separate group of patients with liver cirrhosis (Mosse syndrome).<sup>323</sup> Occlusion of the hepatic veins (Budd-Chiari syndrome) has been observed.<sup>305,330</sup>

### *Splenomegaly*

Splenomegaly occurs in at least three fourths of these patients<sup>301,339</sup> (90% of our erythremia patients). The size of the spleen varies greatly in individual patients and occasionally it may even extend to the pelvic brim.<sup>303</sup> It is usually quite hard and smooth. There may be pain in the splenic region and, following infarction, a friction rub can be heard in this area. It has been assumed that polycythemia antedates the enlargement of the spleen and that engorgement of this organ with blood is the chief cause of the swelling.

### *Respiratory System*

Dyspnea on exertion of great degree is common and hoarseness is not unusual. Respiratory infections are easily acquired by these patients. Massive hemoptysis or hemothorax may occur. Roentgenograms usually reveal prominent vascular markings in the thorax.

In most patients with polycythemia vera the arterial oxygen saturation has been found to be normal, even when the hemoglobin levels have been high, indicating that the high

viscosity of the blood does not prevent the normal saturation of the blood with oxygen.<sup>370,372,413</sup> Breathing oxygen raises the oxygen saturation of the arterial blood to a degree comparable to that observed normally, and the oxygen dissociation curve is normal. High diffusing capacities which were reduced following phlebotomy were found in a number of patients with polycythemia vera.<sup>350</sup> Nevertheless, in another study, hypoxia as evidenced by a low arterial oxygen tension and saturation was observed in the absence of demonstrable coexistent cardiorespiratory disease.<sup>392</sup> In these individuals, ventilation/perfusion ratios were altered and the diffusing capacity was low. It was postulated that this might be the result of an alteration of the pulmonary vasculature due to unrecognized thromboembolism. From these observations it would appear that the measurement of oxygen saturation and tension as a means of differentiating primary and secondary polycythemias could be misleading.

### *Genitourinary System*

Vesical, vaginal, and uterine bleeding have been recorded, as well as a nontraumatic perirenal hematoma.<sup>317</sup> When there is hypertension, albuminuria and signs of renal disease may be found.

### *Neuromuscular System*

Headache is the most common neurologic symptom,<sup>333</sup> but lassitude, vertigo and giddiness, transitory syncope, insomnia, weakness, and a sensation of fullness in the head and numbness and tingling in the fingers, less often in the feet, are very common. As Osler remarked, these symptoms are like those of mountain sickness (page 977).

Visual disturbances are common and include transitory dimness of vision, or even temporary blindness, scotomas, specks and bright points in front of the field of vision, diplopia, and temporary paralysis of one of the eye muscles. On examination of the eye-grounds the vessels are observed to be engorged, tortuous, and irregular in diameter;

the veins are dark purple, the retina deeply colored. Papilledema has been observed and embolism of the central retinal artery has been reported.<sup>307</sup> The cerebrospinal fluid pressure may be increased.<sup>297</sup> Ringing and roaring in the ears are exceedingly common. Ménière's syndrome has been reported.

Vascular lesions of the brain constitute the most serious complication. Various resulting paralyses may be the first symptoms of the disease. Myoclonia, chorea,<sup>313</sup> grand mal attacks, and symptoms suggesting brain tumor, general paresis, and tabes have been associated with polycythemia vera, as well as narcolepsy, attacks of catalepsy, and psychic disturbances of various types (loss of memory, mental depression, confusion, hallucinations, slurring of speech).

Pains in the limbs may be very troublesome and severe. These have been attributed to the pressure on the bone by swollen, hyperplastic bone marrow. Curious paresthesias may be encountered and pruritus may be very distressing. Anatomic evidence of spinal cord changes has not, however, been found at autopsy.

### *Blood*

The venous blood is characteristically dark. It may be so thick that it is drawn up in a pipet with difficulty and spreads slowly between coverglasses. Red cell counts of  $7$  to  $10 \times 10^{12}/l$  are common when patients with this disease are first seen and values as high as  $12$  and even  $15 \times 10^{12}/l$  have been recorded.<sup>57</sup> It is difficult to accept some of the values reported. When red corpuscles are normal in size ( $87$  fl), there is "standing room" only for about  $11.5 \times 10^{12}$  cells/ $l$  and it is inconceivable that anyone could live with blood consisting of all cells and no plasma. We have seen the volume of packed red cells as high as  $0.86$  l/l blood in a patient with congenital heart disease and  $0.81$  l/l in one with polycythemia vera. The highest recorded is  $0.92$  l/l in a patient with polycythemia vera whose red cell count was  $10.37 \times 10^{12}/l$ .<sup>345</sup>

It is not unusual to find that, in patients

with marked polycythemia, MCV is reduced below normal. Usually this reflects the presence of iron deficiency. The average size in 22 of our patients was 80 fl. In one the MCV was as low as 61 fl. Somewhat more than  $16 \times 10^{12}$  cells/l as small as these could be packed in one liter.

Hemoglobin values as high as 40 g/dl ("240%") have been recorded, but the accuracy of such determinations must also be questioned. Values of 18 to 24 g/dl blood are more usual. The hemoglobin may not be increased in proportion to the increase in red cell count, this being the case when MCV and MCH are reduced. Sometimes the hemoglobin content of the red cells is reduced even more than their size (low MCHC), which indicates hypochromia. This is found particularly after large and repeated hemorrhages.

The individual red corpuscles usually appear quite normal. There may be slight anisocytosis, but poikilocytosis is unusual. Polychromatophilia and occasionally basophilic stippling may be found. An occasional normoblast may be observed in the blood smear and such a finding, in the presence of a relatively normal or definitely increased red cell count, should arouse suspicion of polycythemia vera. The reticulocyte count, in percent, is not significantly increased. Following a hemorrhage, however, the reticulocytes may be increased and a number of other immature forms of the red cell series may be encountered. If the hemorrhages are repeated, the morphologic appearance of the red corpuscles may be like that in iron deficiency anemia.

It is curious that neither Vaquez nor Osler appreciated the significance of the moderate or even marked leukocytosis, together with a "shift to the left" in the myeloid series of leukocytes that is often present in the disease named after them. Türk, in 1904, called attention to this significant finding, which suggests that the whole bone marrow is hyperactive rather than the erythropoietic tissue alone. The leukocyte counts were greater than  $10.0 \times 10^9/l$  in half of Osler's patients. In another series of 127 patients the white cell count was elevated in 84%.<sup>402</sup>

Leukocyte counts of  $25.0 \times 10^9/l$  are not uncommon<sup>62</sup> and values above  $50.0 \times 10^9/l$  have been recorded.<sup>371,407</sup> The myeloid leukocytes are relatively as well as absolutely increased, the metamyelocytes are increased in number, and 1 or 2% of myelocytes, sometimes more, are found. Myeloblasts usually are not observed. Basophil, eosinophil or monocyte concentrations may be increased. Leukocytes from polycythemia vera patients exhibit increased metabolic activity.<sup>372a</sup>

The blood platelets are frequently increased, usually in the 500 to  $1,000 \times 10^9/l$  range, but counts as high as 3,000 and even  $6,000 \times 10^9/l$  have been recorded.<sup>303</sup> Bleeding time and conventional coagulation parameters usually are normal, but the clot may retract poorly. It should be noted that the leukocyte and platelet counts are not always increased above normal in patients with otherwise typical disease. Such normal values were found in 20% of the patients in one series.<sup>336</sup>

It is not unusual, however, for morphologic and qualitative functional platelet abnormalities to be detectable. Platelets may appear to be abnormally large and even bizarre-shaped and megakaryocyte fragments sometimes are seen in the blood smear. The hemorrhagic complications of this disease suggest that a hemostatic defect may be present. Physical distention of the vascular bed is a plausible factor to explain excessive bleeding when it occurs. In addition, in some instances a fibrinolytic factor has been demonstrated.<sup>365</sup> Abnormal platelet thromboplastic function has been reported<sup>284,386</sup>, in a study of 29 patients, platelet factor 3 deficiency and excessive friability of the clot were found.<sup>360</sup> It was postulated that poor clot formation may result from the inadequate prothrombin-accelerating property of the platelets. Defects in platelet ADP release and aggregation<sup>373</sup> and in platelet adhesiveness<sup>409</sup> have been described.

Studies of fibrinogen turnover in three patients with erythremia indicated that fibrinogen was consumed in the course of chronic disseminated intravascular coagulation<sup>422</sup>; similar findings were observed in

several patients with erythrocytosis secondary to pulmonary insufficiency.

*Erythrokinetic studies* have shown active hemoglobin production, but otherwise findings have been diverse. Erythrocyte survival may be normal<sup>393</sup> or shortened<sup>401</sup> and splenic sequestration may or may not be present. As measured by the <sup>15</sup>N-glycine method, the rate of hemoglobin production was found to be about 2½ times the normal. There was a marked increase in plasma iron turnover rate.<sup>382</sup> This, incidentally, was not reduced by oxygen administration, as occurs when the polycythemia is due to anoxia.

A lengthened resistance span was described in studies of hypotonic saline fragility.<sup>383,398</sup> Increased serum bilirubin<sup>345,398</sup> and increased urine and stool urobilinogen<sup>401</sup> have been demonstrated in some patients with polycythemia vera, but, when allowance is made for the increase in the total amount of hemoglobin that must be degraded, fecal urobilinogen values rarely are increased above expected values and may, in fact, be somewhat reduced.

*Neutrophil kinetic studies* in patients with polycythemia vera whose neutrophil counts ranged from normal to  $23.9 \times 10^9/l$  showed a blood neutrophil pool that ranged from normal to 12 times normal, with increased margination and a normal or slightly prolonged half disappearance time. The blood neutrophil turnover rate (effective neutrophil production) was usually increased and varied from normal to 5 times normal mean values.<sup>362</sup>

*Platelet kinetic studies* in five patients with polycythemia vera in whom the platelet concentration was increased revealed effective production rates that ranged from 2 to 13 times normal. The marrow megakaryocyte mass was increased in all five patients.<sup>378</sup>

The *viscosity* of the blood may be 5 to 8 times greater than normal.<sup>62,315</sup> The *specific gravity* is 1.075 to 1.080, as compared with the normal range of 1.055 to 1.065. The degree of abnormality varies with the relative quantity of red corpuscles. The viscosity and specific gravity of the serum were found to be actually less than is normal.<sup>400</sup> The eryth-

rocyte sedimentation rate of polycythemic blood is greatly retarded.

**TOTAL BLOOD VOLUME.** This is characteristically increased. The enormous increase in blood, which distends even the smaller vessels of the whole body, accounts, no doubt, for many of the symptoms of this disease. In a group of 30 patients whose volume of packed red cells was 0.55 l/l or greater, the total red cell volume, measured by the <sup>32</sup>P-labeled red cell method, was 38.8 to 93.9 ml/kg body weight as compared with the normal average of 29.9 ml/kg.<sup>364</sup> In two thirds of these patients the plasma volumes were below the lower limits of normal and in none was the plasma volume above normal. Similar observations have been made by the <sup>51</sup>Cr method.<sup>336</sup> Because of variations in plasma volume, the volume of packed red cells gives only a rough indication of the size of the red cell mass.

### *Bone Marrow*

The marrow is dark red and very cellular. The hyperplasia involves all the marrow elements, however, so that the ratio of the different types of cells to one another is not strikingly different from the normal. The percentage of nucleated red cells may be moderately elevated.<sup>61,414</sup> These cells may be either orthochromic normoblasts or of less mature type, but megaloblasts are not found. There may be more myelocytes and myeloblasts than is normal and an unusual number of eosinophilic and basophilic leukocytes may be found. Megakaryocytes are sometimes more numerous than is normal and may be larger than normal.<sup>378</sup> In a series of 19 untreated patients, no marrow iron could be demonstrated.<sup>306</sup>

On biopsy, general hyperplasia with replacement of adipose tissue by hematopoietic cells is evident<sup>62</sup> and clumps of stem cells and basophilic erythroblasts are seen.<sup>368</sup>

### *Other Findings*

The *urine* may be normal, but albuminuria is found not infrequently and, less often, casts

are present.<sup>62</sup> The increased urobilinogenuria found in some of the patients has been mentioned previously. Studies of renal hemodynamics suggested that glomerular filtration, in spite of the decreased fraction of plasma in the blood, is kept at almost normal values by an increase in renal blood flow and in the proportion of plasma filtered.<sup>412</sup>

The amount of uric acid in the serum may be normal or increased. Hyperuricemia was present in 70% of one series of 127 patients. In another series of 47 patients, values from 2.8 to 11.7 mg% were found (average 6.6 mg%).<sup>62</sup> Secondary gout occurs in 5%<sup>304,336</sup> or more of these patients.<sup>336,341,402,496</sup> The occurrence of hyperuricemia in polycythemia vera is attributable to overproduction of uric acid.<sup>408,415</sup> When urinary uric acid was labeled cumulatively with <sup>15</sup>N-glycine, a sharp contrast was noted between the rapid peak of isotope incorporation into uric acid in primary gout and the slow incorporation in secondary gout.

A vitamin B<sub>12</sub> binding protein, which may be an altered form<sup>369</sup> of transcobalamin I (Chapter 4), has been found in the plasma of patients with polycythemia vera<sup>376</sup> and in a variety of conditions involving leukocytosis.<sup>369</sup> This may explain the observation that, whereas serum B<sub>12</sub> content may be within the normal range, or only moderately elevated, the capacity of the serum to bind additional vitamin B<sub>12</sub> added in vitro (unsaturated B<sub>12</sub> binding capacity, U B<sub>12</sub> BC) is increased.

Spurious hyperkalemia has been noted when the platelets have been greatly increased in number.<sup>399</sup> Hyperhistaminemia and hyperhistaminuria were reported in two thirds of a series of patients with polycythemia vera<sup>478</sup> and this may partly explain the pruritus often present (page 990). The basal metabolic rate may be increased moderately.<sup>367</sup> Gastric acidity may be normal or increased, or there may be anacidity.

### Cytogenetics

Few satisfactory reports of cytogenetic findings in untreated patients with polycythemia vera are available. Such as they are,

they are inconsistent. Some investigators have reported normal results.<sup>388,389</sup> Others found some degree of aneuploidy in 7 of 11 patients.<sup>387</sup> In still another study, an extra C-group chromosome was found in marrow cells of about 10% of the patients.<sup>396</sup> In treated patients, extensive chromosome abnormalities have been described.<sup>387,394</sup>

### Diagnosis

The characteristic color of the skin of patients with polycythemia vera may not be so striking that its significance is recognized at once, and the spleen is not always enlarged. Furthermore, the symptoms are so varied that a great number of diseases, particularly those of the cardiovascular and nervous systems, may be simulated. The first manifestations may suggest peripheral vascular disease (thromboangiitis obliterans, erythromelalgia), or gastrointestinal disease (peptic ulcer), gout, or some wholly unrelated disorder; or the symptoms may be so numerous and unrelated that neuroasthenia may be considered.

However, when the classic triad—ruddy cyanosis, splenomegaly, and polycythemia—is present, making the correct diagnosis should not be difficult. Furthermore, morphologic signs of accelerated erythropoiesis, such as occasional normoblasts in the blood smear and some polychromatophilia, often are present. In addition, as mentioned previously, leukocytosis, with moderate shift to the left, and thrombocytosis are found in 67 to 80% of the patients.

When splenomegaly and signs of bone marrow activity involving all three morphologic elements of the blood are present and the degree of polycythemia is not great, the possibility that one is dealing with an early stage of chronic myelocytic leukemia or of myelofibrosis must be considered. Rare cases of chronic myelocytic leukemia which, in their early stages, were characterized by slight polycythemia rather than anemia have been described.<sup>361,406</sup> Then again, if gastrointestinal bleeding or hemorrhage from another source has taken place and its severity has not been fully appreciated, the finding of

anemia together with leukocytosis, thrombocytosis, and splenomegaly may lead to a diagnosis of leukemia which only is recognized as mistaken after sufficient time has elapsed for red cell regeneration to restore the previous polycythemic levels. Further difficulties in differential diagnosis arise from the fact that, in polycythemia vera, the leukemoid manifestations may be so pronounced that the picture of chronic myelocytic leukemia is very closely simulated. This was true in 10% of one series of 163 cases<sup>138</sup> and in 40% of 127 cases in another.<sup>402</sup>

The *leukocyte alkaline phosphatase* (LAP) test (page 1279) may be of help in differentiating polycythemia vera with an associated leukemoid reaction from chronic myelocytic leukemia since values above normal may be found in the former and lower values are found in CML. Thus the LAP score was elevated on at least one occasion in all 74 patients with polycythemia vera tested in one series. Also the LAP score was elevated in two patients presenting with features suggesting chronic myelocytic leukemia in whom the subsequent picture was that of polycythemia vera.<sup>402</sup> In another series of 25 patients with polycythemia vera, high, abnormal scores were found in 20 and normal values were obtained in five, four of whom were in the early stages of the disease.<sup>406</sup> In a smaller series of 20 patients, followed with serial observations over a six-month period, during which they were in remission as a result of treatment, only eight subjects had elevated LAP scores; 11 fell within the normal range.<sup>361</sup> It has been reported that patients treated with busulfan had LAP scores that were lower than the average for the erythremic group.<sup>402</sup> In one patient with a low LAP score, the Ph<sub>1</sub> chromosome was demonstrated in the marrow<sup>361</sup>; after a 3½-year course closely simulating polycythemia vera this patient developed a rapidly evolving leukemic picture and died within a month.

Much greater difficulty in differential diagnosis arises when splenomegaly is not present and leukocytosis and thrombocytosis are not found; this, as mentioned earlier, may be the situation in perhaps 20 to 30% of

patients with polycythemia vera. In such patients the red cell mass should be measured, and if elevated the various causes of erythrocytosis, discussed in the first part of this chapter, must be considered. Pulmonary and cardiac function studies, a LAP test, measurement of  $P_{50}$  (page 982), and an intravenous pyelogram are then indicated and should help to establish the diagnosis. In most instances of erythrocytosis, normoblasts are not found in the blood and leukocytosis and thrombocytosis are not present. Thus, in a series of patients with congenital heart disease, slight leukopenia with a slight absolute decrease in the number of eosinophils, monocytes, and lymphocytes was found.<sup>141</sup> However, normoblasts have been described in the peripheral blood of patients with congestive heart failure<sup>432</sup> and, therefore, this finding alone cannot be taken as evidence of polycythemia vera. Even the coexistence of gout does not indicate that one is dealing with polycythemia vera since gout has been observed in erythrocytosis secondary to congenital heart disease.<sup>431</sup>

In view of the age incidence of polycythemia vera it may be expected that a certain proportion of the patients may also have chronic pulmonary or cardiac disease and these may be contributing in a minor way to the polycythemia. Measurement of red cell mass and total blood volume will help to separate absolute from relative polycythemia but this will not exclude the various causes of true erythrocytosis mentioned above. In these "secondary" forms of polycythemia, the total blood volume and red cell mass may be increased as much as in polycythemia vera.<sup>62</sup> The measurement of arterial oxygen saturation and tension (page 979) has not been as helpful in differential diagnosis as one would expect, but  $P_{50}$  measurement should distinguish cases due to increased oxygen affinity. The fact that various tumors may produce erythrocytosis adds to the diagnostic problems arising in some instances, since some tumors may not be demonstrated readily. An intravenous pyelogram should be performed to rule out the possibility of renal causes of erythrocytosis (page 986), but other causes

are less easily detected. The leukocyte alkaline phosphatase may be helpful, as already mentioned.

"Gaisböck's syndrome"<sup>54</sup> and "stress erythrocytosis" have been the source of considerable confusion. They were fully discussed in an earlier section of this chapter (page 976).

## Treatment

### General Remarks

As long as the cause of polycythemia vera is unknown, treatment must be symptomatic. A number of methods have been recommended to relieve the symptoms of this disorder. Relief of most of the symptoms is accomplished by lowering the red cell mass and total blood volume. This can be done by removing blood (venesection), by destroying red cells *in vivo* (phenylhydrazine), or by suppressing blood production in a variety of ways (irradiation; chemotherapeutic agents). In choosing a method of treatment the object should be to produce a reduction in the blood volume by means that: (1) have the smallest chance of causing harm; (2) permit the longest survival; (3) permit the greatest proportion of time at work and recreation; and (4) are least expensive and inconvenient for the patient. The choice of a method is relatively simple if the above objectives are kept clearly in mind.

### Venesection

Venesection offers prompt and effective restoration of the red cell mass and blood volume to normal. Many patients can be maintained in an essentially normal state by phlebotomy together with a few simple adjuvants, when necessary, to control hyperuricemia or pruritus.<sup>509</sup>

In criticism of venesection, it has been stated that the method is somewhat troublesome, leukocytosis and thrombocytosis are not controlled, and erythropoiesis is stimu-

lated by the blood loss. The last objection has not been substantiated<sup>445</sup>; presumably reticulocytosis does not occur after adequate phlebotomy because the blood is removed from the body and iron deficiency is induced.

Venesection has been used primarily for its immediate effects in relieving symptoms, especially vertigo, fullness in the head, headache, tinnitus, mental torpor, weakness, and pain in the bones, muscles, or joints. If 500 ml are removed repeatedly at one- to three-day intervals it is possible to reduce the blood volume to normal (usually after 6 to 8 units have been removed), thereby producing a remission that may last several, even 15, months.<sup>445</sup> In patients over 65 or in those with evidence of vascular complications,<sup>509</sup> smaller phlebotomies with infusion of plasma<sup>475</sup> or dextran<sup>16</sup> to maintain the blood volume while reducing the blood viscosity and red cell mass have been advocated. However, except in the presence of congestive failure or in the face of impending vascular thrombosis in patients with very high hematocrit values, as suggested by transient ischemic attacks or angina (page 976), too aggressive therapy is best avoided in this relatively benign disease.<sup>509</sup> Generally, patients are comfortable if the volume of packed red cells is brought to the upper levels of normal rather than to still lower levels. Venesection can be used as the sole therapeutic measure in perhaps two thirds of the patients,<sup>509</sup> at least for time. Good control can be maintained by one or two 500-ml phlebotomies every three or four months. In India, patients with polycythemia vera were successfully treated by producing hookworm infection and iron deficiency.<sup>468</sup> When phlebotomy is required more often than once every two months it is generally preferable to resort to other forms of therapy. Of those that will be described below, the agent most generally preferred is radioactive phosphorus.<sup>509</sup>

The employment of an iron-free diet<sup>498,509</sup> or other dietary regimens has not been very successful and imposes unnecessary hardship on patients with so chronic a disease as polycythemia vera.

**Phenylhydrazine**<sup>476,489,491</sup>

Phenylhydrazine is a base related to antipyrine and was prepared on a large scale from the anilin used commercially to produce antipyrine. It was introduced for the treatment of polycythemia vera by Eppinger and Kloss in 1918. The liquid form is unstable, but the crystalline hydrochloride is less easily decomposed unless exposed to air. The drug was given in capsules, usually in amounts of 0.1 to 0.3 g/day up to a total dose of 1.5 to 3.5 g.<sup>477</sup> It is no longer used in this way because of its gastrointestinal and other toxic effects and the danger of producing severe hemolytic anemia.<sup>485</sup> It rarely is used even as adjuvant therapy to maintain remissions. In doses of 0.1 g/day several times per week, however, the toxic effects are minimal. Phenylhydrazine also may be useful in patients in whom thrombocytopenia develops after radiophosphate therapy. In contrast to phlebotomy the products of destruction of the red cells (chiefly iron) remain within the body and are utilized again.<sup>438</sup>

**Irradiation**

Irradiation, in one form or another, has been used as a method of treatment for many years. Radiation was first directed to the spleen, without benefit.<sup>494</sup> Irradiation of the bones was first successfully applied in 1916.<sup>490</sup> Deep roentgen therapy, irradiation of the whole body ("spray therapy," "total radiation"),<sup>501</sup> and radium as well as thorium-x have been used.<sup>497</sup> Irradiation is relatively slow in action, requires special apparatus as well as skill, and the effect produced, if greater than expected, may be irreparable. On the other hand, the remission produced with successful irradiation may be relatively prolonged. Of the forms of irradiation therapy, most satisfactory is radioactive phosphorus, which causes no nausea or vomiting and can be administered easily.

**Radioactive phosphorus (<sup>32</sup>P)**<sup>495</sup> is usually provided as the dibasic sodium salt. It is soluble in water and, while it is effective

when given by mouth,<sup>513</sup> it has been used more successfully when given by vein.

<sup>32</sup>P passes to tissues that have a high phosphorus content and metabolize phosphorus rapidly. Its uptake by rapidly dividing cells is greater than that by normal cells. Since the physical half-life of this isotope is 14.3 days, steady irradiation of tissue takes place for several weeks.<sup>473</sup> Its concentration in bone makes <sup>32</sup>P particularly valuable in the management of hematopoietic disorders. Among these its value has been greatest in the management of polycythemia vera.

<sup>32</sup>P induces satisfactory clinical and hematologic remissions in polycythemia vera and *these have lasted as long as one to two or more years.*<sup>315,483</sup> As with roentgen therapy, the fall in the red cell count does not usually begin before 30 to 60 days after <sup>32</sup>P has been given. Care must be taken to avoid producing anemia, leukopenia, or thrombocytopenia. Unlike the effects of roentgen therapy, radiation sickness does not develop.

A recommended method of treatment is as follows: The VPRC is brought down to 0.55 l/l, or lower, by phlebotomies. The patient is then given between 3 and 5 millicuries (mCi) of <sup>32</sup>P, intravenously or 2.3 mCi/m<sup>2</sup>.<sup>448</sup> No additional <sup>32</sup>P is given for three months, in order to avoid cumulative effects. If the VPRC rises above 0.55 l/l in the interval, venesection can be performed. If, after three months, the VPRC still is above 0.55 l/l, a second injection of 1 to 4 millicuries is given. Examinations are repeated at three-month intervals. Some patients do not require a second injection or further phlebotomies for 6 to 18 months or longer. Perhaps 10% of patients will need a third injection. After this, it has been recommended that no further injections be given for at least a year, preferably 18 months.<sup>495</sup>

An analysis of 300 courses given to 139 patients showed that an average of 6.7 mCi had been given in a "course," as represented by a six-month period.<sup>62</sup> The majority of these patients were retreated within intervals of 6 to 10 months. In another series of 241 patients<sup>501</sup> the average dose required to pro-

duce remissions was 5.7 mCi in patients without leukocytosis or myeloid immaturity and as much as 8.3 mCi in others. The range of dose required was 3 to 21 mCi.

Some of the pros and cons of radiation as compared with other forms of therapy have been discussed previously (page 997). In addition, as large series of patients treated with radiophosphate have accumulated,<sup>436,440,506,509</sup> an incidence of leukemia of perhaps 10 to 15% has become apparent. It is not yet clear whether this is because patients so treated have survived long enough to develop leukemia, which some observers believe may be part of the natural evolution of this disorder,<sup>436,509</sup> or because it is a direct effect of irradiation treatment.<sup>323,440</sup> It is noteworthy that damage to chromosomes was shown to occur following treatment with <sup>32</sup>P, but this is not a consistent finding and aneuploidy has been described even in untreated subjects.<sup>337,394</sup>

When the incidence of leukemia in polycythemia vera patients treated with <sup>32</sup>P was first publicized, there was at first a trend against the use of this therapy. In time, however, after it was realized that this treatment is so simple and effective, morbidity is so low, and survival is so prolonged when the therapy is used wisely, <sup>32</sup>P came again to be regarded as a very useful therapeutic agent. A combination of phlebotomy and, when necessary, modest doses of radiophosphate (or perhaps other myelosuppressants)<sup>448</sup> provides a simple and effective mode of therapy in most patients. The median survivals in patients so treated have ranged from 10 to 14.5 years.<sup>62,483,506,509,511</sup>

Whether or not to take the risk of acute leukemia developing, perhaps as an ultimate (and as yet unproved) ill effect of <sup>32</sup>P therapy, must be a decision for the physician and his patient to make. Until data from a well-controlled clinical trial have become available or some other and better form of therapy has been devised, we believe that the use of <sup>32</sup>P in the treatment of polycythemia vera is justified in most cases. However, it has always been our practice to use the minimum

amount of <sup>32</sup>P that is practical in a given patient. This approach is now supported by the evidence that the risk of acute leukemia appears to be dose dependent.<sup>440</sup>

### Chemotherapy

In the past, various chemotherapeutic agents have been used for the treatment of polycythemia vera. Benzene was once used<sup>456</sup> but was found to be too toxic. Fowler's solution (potassium arsenite) was found to lower the blood count in some of the patients<sup>472</sup> as did nitrogen mustard,<sup>502</sup> triethylene melamine (TEM),<sup>499</sup> and thiotepea.<sup>471</sup> Given orally, TEM produced satisfactory remissions in 20 of 30 subjects, with remissions lasting eight or nine months. However, thrombocytopenia was a frequent complication. The antimalarial drug pyrimethamine was shown to have an effect in this disease.<sup>474</sup> A neutral piperazine (Vercyte) was also found to be effective.<sup>492</sup> However, none of these agents has survived the test of time.

Because of the possibility that <sup>32</sup>P may be responsible for the ultimate development of leukemia in patients so treated, as discussed under the foregoing heading, there has been a resurgence of interest in the management of polycythemia vera with chemotherapeutic agents.<sup>469,487,507,509</sup> Busulfan (4 to 6 mg/day given orally) has been the most preferred agent,<sup>467,509</sup> but has proved to be much more effective in controlling the leukocytosis and thrombocytosis than in the management of the erythrocytosis.<sup>467</sup> It tends to produce excessive and prolonged leukopenia and thrombocytopenia in many patients, and occasionally marrow aplasia and other complications such as skin pigmentation and pulmonary fibrosis.<sup>487</sup> Chlorambucil (6 to 8 mg daily) has been recommended for patients with normal or low platelet and leukocyte counts; cyclophosphamide (100 to 150 mg/day) also may be useful in these patients.<sup>487,509</sup> Melphalan produced excellent initial results in 24 of 27 patients; its side reactions were infrequent.<sup>487</sup> Other chemotherapeutic agents have also proved effective

in limited trials.<sup>469,507</sup> All such agents carry the disadvantage that their use requires much more frequent supervision than is necessary when <sup>32</sup>P is employed. In addition, it is known that these agents, like <sup>32</sup>P, may favor the development of somatic mutations. Occasionally, leukemia has been reported as developing in patients treated with busulfan.<sup>436,448</sup> It is still too early to ascertain whether use of this drug or of other chemotherapeutic agents will decrease the incidence of leukemia or the myeloid metaplasia-myelofibrosis transformations that develop after <sup>32</sup>P therapy. A prospective study under the sponsorship of the National Institutes of Health is under way and it is hoped that this will provide the answer to such questions.<sup>448</sup>

### *Splenectomy*

Splenectomy has been performed in a number of polycythemia vera patients. It is not only valueless, but may be harmful; death has followed in a number of instances.<sup>484</sup>

### *Treatment for Relief of Miscellaneous Symptoms*

Hematologic control, especially if accomplished by myelosuppressive therapy, usually relieves the various manifestations of polycythemia vera and improves the performance status of the patient. However, certain symptoms may persist to some extent and require treatment.

**PRURITUS.** The pruritus, upper gastrointestinal distress, and urticarial manifestations of polycythemia vera were found to correlate with increased levels of whole blood histamine, which, in turn, was roughly related to the basophil leukocyte count.<sup>478</sup> These clinical manifestations were controlled by the administration of a potent antihistaminic, cyproheptadine (4 mg three or four times per day), in 12 of 18 patients so treated.<sup>478</sup> This observation, if confirmed, would favor the use of myelosuppressive agents in the treatment of polycythemia vera since these produce a reduction in histamine levels whereas phlebotomy does not.

**HYPERURICEMIA.** The common occurrence of hyperuricemia and gout in patients with polycythemia vera has been mentioned earlier in this chapter. Because of the excessive urinary load of uric acid excreted by patients with "myeloproliferative disorders,"<sup>511</sup> urate may be precipitated in the kidneys, leading to stone formation or nephropathy. In one series, urolithiasis occurred in 40% of 44 patients with secondary gout as compared to 20% of 937 patients with primary gout.<sup>482</sup> An effective means of reducing uric acid production in polycythemia vera, other than by myelosuppression, is by the use of allopurinol in doses of about 300 mg per day.<sup>514</sup> However, although this drug has been given for longer than one year to some patients with minimal side effects,<sup>514</sup> its use should probably be restricted to short periods when the avoidance of uric acid deposition in patients starting on therapy is a major concern. For long-term management, adherence to the general principles of the treatment of gout is recommended.<sup>465,490</sup>

### *Course and Complications*

The course of polycythemia vera is chronic, but various complications may develop. When the high incidence of vascular complications is avoided by appropriate therapy the course usually is characterized by periods of remission with few, if any, symptoms, interspersed with more or less asymptomatic relapses that again respond to treatment. Intercurrent infections may be frequent, especially those of the respiratory tract. Bronchitis and emphysema may develop. Elevated levels of IgM and IgG may be found.<sup>439</sup> The association with duodenal ulcer, gout, hypertension, and cirrhosis of the liver has been mentioned previously. In patients with hypertension, chronic renal disease and arteriosclerosis are common. Albuminuria may be present, possibly as the result of blood stasis in the kidneys. In view of the frequent finding of an increased basal metabolic rate, it is of interest that hyperthyroidism has been reported in only one well-studied case.<sup>315</sup> Various other conditions associated with polycythemia vera have been

reported from time to time; these include paroxysmal hemoglobinuria,<sup>442</sup> agranulocytosis,<sup>444</sup> chronic lymphocytic leukemia,<sup>425</sup> lymphoma, multiple myeloma,<sup>435</sup> hemoblastic sarcoma,<sup>443</sup> and osteosclerosis,<sup>407</sup> as well as termination with a picture resembling that of aplastic anemia,<sup>428</sup> pernicious anemia,<sup>429</sup> or leukoerythroblastic anemia.<sup>446</sup> Termination of polycythemia vera in leukemia and in myelofibrosis will be discussed shortly. The "acute erythremia" of di Guglielmo is quite different from the disorder under discussion here. Its course is acute and the condition is characterized by anemia and marked erythroblastosis (page 1475).

Eventually, in perhaps 25% of polycythemia vera patients, there is a progressive reduction in erythrocyte survival, unaccompanied by adequately increased erythropoiesis, and myelofibrosis (Chapter 57) develops.<sup>430,436</sup> Extramedullary hematopoiesis takes place in the spleen and elsewhere, including the liver. A rising leukocyte count, often with increased immature myeloid forms, accompanies these changes and tear-drop forms and nucleated red cells appear in the blood.<sup>436</sup> The spleen may enlarge dramatically. About one third of such patients ultimately develop a picture simulating that of acute myeloblastic leukemia.<sup>436</sup> Others gradually become more anemic and thrombocytopenic and die of a variety of intercurrent complications in the "spent phase" of myeloid metaplasia.<sup>448</sup> Still other patients (perhaps 15%) develop an acute leukemia-like picture without preceding evidence of myeloid metaplasia or myelofibrosis.<sup>436</sup> Whether these changes are the result of irradiation therapy or reflect the natural evolution of the disease when early death from thrombosis or hemorrhage is avoided is moot, as was discussed earlier in this chapter. In certain studies the finding of abnormal chromosomes in about 10% of untreated patients has been cited to support the suggestion that a subgroup of patients with polycythemia vera possesses a propensity for cytogenetic accidents and perhaps these are the patients destined to develop leukemia.<sup>436,448</sup>

## Prognosis

The prognosis in polycythemia vera in the absence of treatment is not easily determined. In one review of 250 patients who died between 1933 and 1961<sup>426</sup> it was found that 50% of 49 untreated patients died within 18 months after the onset of the first symptom or sign (Fig. 30-11). Thrombosis was the cause of death in 100 of the 250 patients in that series, while death resulted from hemorrhage in only 15 patients. Myelofibrosis developed in 14, leukemia in 9, and other forms of anemia in 6. Half of the 62 patients treated with venesection died after 3½ years. Of the 48 treated by x rays, half were alive 12½ years after the first sign of the disease. This is consistent with median survival figures of 11.5,<sup>440</sup> 13.6,<sup>402</sup> and even 16<sup>506</sup> years reported by others. In another study it was found that thromboses occurred much less frequently (4.2%) in patients treated successfully with radioactive phosphorus<sup>415</sup> than prior to the introduction of this form of therapy when thrombosis occurred in approximately 25% of the patients.

The benefits of adequately controlling the disease can also be seen in the reduction of deaths and complications following surgical procedures necessary for associated problems. Thus, in 62 major operations performed in patients with polycythemia vera, the incidence of postoperative complications (mainly thrombosis and hemorrhage) in inadequately controlled patients was 83% as compared to 21% in patients with normal hemoglobin values. A long period of effective control preoperatively was associated with only 6% complications as compared to 33% for patients controlled for only a short time.<sup>449</sup> The incidence of postoperative deaths was also dramatically reduced from 37% to 5% as the result of adequate preoperative control.

Survival following treatment with <sup>32</sup>P has been the subject of much discussion and, unfortunately, there is no agreement. Osgood concluded that the survival time of <sup>32</sup>P-treated patients was about four years longer than for patients treated by other methods.<sup>325</sup> Others found no difference between the sur-

Fig 30-11 Percentage survival for patients with polycythemia vera

— untreated	49 patients
..... venesection only	62 patients
- - - - - $^{32}\text{P}$ and/or chlornaphazine	52 patients
- - - - - x-ray therapy only	48 patients
- · - · - various combinations of x-ray therapy	36 patients

(From Chievitz and Thiede <sup>426</sup> courtesy of the authors and the Acta Medica Scandinavica)

vival of patients treated with x ray or  $^{32}\text{P}$  as compared with those treated with other effective modes of therapy.<sup>402,433</sup> Modan and Lilienfeld,<sup>440</sup> on the basis of their survey, came to the same conclusion. The results of a well-controlled clinical trial on the basis of which a wholly reliable conclusion can be based have yet to be published.<sup>609</sup>

Although in one of the above-mentioned investigations no cases of leukemia were observed among 107 patients treated by radiation or in 117 treated without radiotherapy,<sup>433</sup> in Modan and Lilienfeld's and in Osgood's studies the incidence of acute leukemia as a terminal event was found to be higher among patients treated with irradiation than among those not so treated (perhaps 9:1).<sup>440</sup>

Whatever the solution to the questions raised above may be, there is no doubt that the life expectancy and well being of patients with polycythemia vera whose disease has been wisely managed have been greatly prolonged, as compared with the outcome of untreated patients. This is consistent with our experience.

## Pathology

The extreme plethora, the engorgement of all the organs with blood which flows, when the heart is removed, "as if from an inexhaustible spring,"<sup>526</sup> and the enlarged and thrombosed veins as well as the unusual color of the skin and the large and small hemorrhages in the skin, mucous membranes, brain, meninges, serous cavities, and the various organs make up a striking and characteristic picture.

The spleen is enlarged, smooth, moderately hard, and dark bluish-red and may contain infarcts, thromboses and cysts produced by hemorrhage. The follicles are atrophied and the pulp hypertrophied and hyperemic. The spleen is crowded with red corpuscles, but a few foci of extramedullary hematopoiesis containing nucleated red cells are often seen. Tuberculosis has been found in the spleen in a number of the patients,<sup>528</sup> including two of our own.

The liver is often enlarged and is strikingly hyperemic. Myeloid metaplasia may be found.<sup>436</sup> Cirrhosis may be discovered. Renal changes are absent, unless chronic renal disease has been associated, and there may be no cardiac hypertrophy. No remarkable changes are seen in the lymph nodes as a rule, although there may be deposits of hemosiderin, and hematopoietic foci have been observed.

The bone marrow has been described (page 994). It is red in the long bones as well as in the short and flat bones, but in the former it is engorged chiefly with mature erythrocytes, whereas in the short bones there is evidence of active hematopoiesis.<sup>345</sup>

## Introduction

### Cyanosis

The term "cyanosis" refers to a bluish color of the skin and mucous membranes. The color of these tissues depends on the pigment contained therein, the degree of dilatation or contraction of the blood vessels circulating in them, and the color of the fluid in the vessels. The color of the blood depends on the quantity and nature of the hemoglobin carried in the red blood corpuscles. A bluish color develops when there is an increase in the amount of reduced hemoglobin or of hemoglobin derivatives in the red cells.

Cyanosis usually is most marked in the lips, nail beds, ears, and malar eminences. Most commonly it is due to the presence of excessive amounts of reduced hemoglobin, much less often to the presence of other hemoglobin derivatives. As a general rule, cyanosis becomes apparent when the mean capillary concentration of reduced hemoglobin exceeds 5 g/dl. However, it is the absolute rather than the relative amount of reduced hemoglobin which is important in producing cyanosis. For this reason, if the same proportion of hemoglobin is reduced, cyanosis will be more evident when the total hemoglobin level is high, as in polycythemia, than when anemia exists.

In contrast to reduced hemoglobin, concentrations of only 1.5 to 2.0 g/dl of methemoglobin and as little as 0.5 g/dl of sulfhemoglobin will produce the degree of cyanosis associated with 5 g/dl of reduced hemoglobin at normal hemoglobin levels.

Decreased arterial oxygen saturation may result from impaired pulmonary or cardiac function, the presence of anatomic shunts (as in congenital heart disease), decreased atmospheric pressure, or alteration in the oxygen-combining capacity of the hemoglobin. The physiology of hemoglobin was discussed in Chapters 3 and 4 and the effects of decreased atmospheric pressure in producing polycythemia were considered in Chapter 30. In

Fig 31-1 Steps in the oxidation of hemoglobin (simplified and schematic)  
SHb refers to sulfhemoglobin

the case of the hemoglobin derivatives, methemoglobin, sulfhemoglobin and carboxyhemoglobin, decreased oxygen saturation is due to the fact that these compounds are incapable of combining with oxygen.

Long-standing cyanosis dating from birth and unaccompanied by obvious cardiac and pulmonary disease was first reported by Francois in 1845.<sup>76</sup> Although it was appreciated that cyanosis could be induced by "blood poisons," it was 1891 before Dittrich<sup>76</sup> emphasized that methemoglobinemia tended to disappear spontaneously without any alteration in the concentration of circulating erythrocytes, thereby suggesting the existence of a reducing mechanism in erythrocytes. At the turn of the century, the concept of "auto-toxic enterogenous cyanosis," a disorder attributed to the formation of intracellular methemoglobin or sulfhemoglobin by toxic substances, possibly of bacterial origin absorbed from the gastrointestinal tract, was introduced. Ultimately it was recognized that methemoglobinemia could be observed in the absence of exposure to drugs, chemicals, or gastrointestinal disease, and by 1932 a familial incidence of idiopathic cyanosis was reported (Hitzenberger).<sup>76</sup> Hörlein and Weber, in 1948, described a German family in which hereditary methemoglobinemia appeared to be transmitted as a dominant characteristic.<sup>73</sup> The abnormality was shown to be in the globin moiety<sup>110</sup> and thus the first hemoglobinopathy was recognized. Subsequently, Scott and Hoskins<sup>104</sup> noted a high incidence of hereditary methemoglobinemia in Alaskan Eskimos and Indians, and Scott with Griffith,<sup>103</sup> in the following year, reported the absence of an enzyme, later called NADH-methemoglobin reductase (diaphorase), in the erythrocytes of these people.

"Enterogenous cyanosis" is no longer considered to be an entity. Cases reported as such can best be explained by analgesic drug ingestion. Patients ingesting commonly used analgesic and antipyretic drugs, such as acetanilid and phenacetin, which produce methemoglobinemia and sulfhemoglobinemia, not infrequently are neurotic and may deny drug use, but examination of the urine is likely to reveal metabolites of such drugs.<sup>36</sup> Yet the concept of enterogenous cyanosis persists. Experimental evidence has been reported that bacterial overgrowth in the intestine can cause oxidative damage to red cells. Such an effect could make erythrocytes more susceptible to the action of oxidant drugs.<sup>49</sup>

### Oxidation of Hemoglobin<sup>41</sup>

The iron of the heme moiety of hemoglobin has been considered to be in the ferrous state to permit reversible binding and transportation of oxygen. It has been assumed that, when hemoglobin is exposed to oxidants, the divalent (ferrous) iron is oxidized to the trivalent (ferric) state, forming methemoglobin. This concept for oxyhemoglobin has been challenged<sup>48</sup> and evidence which supports the view that the heme iron of oxyhemoglobin is in the ferric low spin state has been published.<sup>50</sup> The nonreactivity of the superoxide which is formed is preserved because of the location of the oxygen-binding site in a very hydrophobic region of the globin polypeptide chain (Chapter 4). Thus, methemoglobin may be formed by the dissociation,  $\text{HbO}_2 \rightarrow \text{MHb} + \text{O}_2^-$ , as distinguished from the commonly accepted manner described above and in Figure 31-1. This does not preclude other means of formation of methemoglobin, such as the direct

oxidation of the ferrous heme of deoxyhemoglobin by various drugs and chemicals.<sup>78</sup>

Methemoglobin can be converted to hemoglobin by reducing mechanisms in the erythrocyte (Chapter 3). Several metabolic pathways can be used for such conversion, but all of them are linked to the regeneration of reduced pyridine nucleotides. The major pathway involves a NADH-methemoglobin reductase. Another is thought to involve direct nonenzymic reduction of methemoglobin by reduced glutathione (GSH) when the hexose monophosphate shunt pathway (Chapter 3) is inactive.

Further oxidation of hemoglobin leads to the production of still other pigments. These are not well defined chemically, but all are forms of irreversibly denatured hemoglobin with heightened absorption of red light.<sup>21</sup> They include sulfhemoglobin, verdoglobin, and choleglobin. The exact nature of sulfhemoglobin remains to be determined. It is a brown to green hemichrome and is defined only by its solubility and its spectral absorption band at 620 nm, a band which does not disappear upon the addition of cyanide. Additional oxidation leads to rupture of the heme-globin linkage and intracellular precipitation of Heinz bodies, which in turn are removed by the spleen (Chapter 5). Thus, an overlapping series of reactions takes place as hemoglobin is oxidized.<sup>1</sup>

What factors determine the relative proportions of methemoglobin, sulfhemoglobin, and other compounds which are formed are not well understood. They include the nature of the oxidant; the intrinsic protective mechanisms of the red cell; whether or not these mechanisms are intact, waning as an effect of aging,<sup>21</sup> or absent as the result of genetic deficiency; and possibly altered as the effect of other factors, including the availability of sulfide.

## Methemoglobinemia<sup>20</sup>

As discussed in Chapter 3, methemoglobin formation occurs *in vivo* at a rate of about 3% a day. This is counterbalanced by a more rapid reduction process. However, under cer-

tain circumstances these mechanisms may be overcome.

### Acquired Methemoglobinemia<sup>5,14,41</sup>

Various chemical compounds used in the home or in industry, or as therapeutic agents, can cause methemoglobinemia (Table 31-1). These compounds or their breakdown products, if present in sufficient amounts, overcome the normal reducing mechanisms. Infants have been found to be especially susceptible to methemoglobinemia, probably because of transient deficiency of the enzyme, NADH-methemoglobin reductase (diaphorase). Perhaps other factors, such as a greater susceptibility of fetal hemoglobin to the action of nitrite as compared with that of adults, also may play a role.<sup>20</sup>

### Causes

A number of substances are capable of oxidizing hemoglobin directly and will do so *in vitro*. These include nitrites, nitrates, chlorates, and quinones. The nitrates, when ingested, are reduced to nitrites in the intestinal tract. Poisoning, sometimes fatal, has been reported a number of times, for example, as the result of the drinking, by infants, of well water high in nitrates<sup>6,25</sup> or of milk prepared by mixing the dried product with water containing nitrates. Nitrites may be absorbed following the use of bismuth subnitrate, ammonium or potassium nitrate, silver nitrate in the treatment of burns,<sup>10,39,45</sup> or the ingestion of foods high in nitrates or food adulterated with nitrites.<sup>28,30,37,43</sup> Methemoglobinemia also has been reported following renal dialysis performed in the home when nitrate-contaminated well water was used.<sup>7</sup>

An indirect effect is postulated in the case of certain aromatic amino and nitro compounds, including acetanilid (Bromo Seltzer), phenacetin (APC, Empirin, Anacin, Stanback), sulfonamides, and anilin dyes.<sup>5,14</sup> Most of these agents do not form methemoglobin from hemoglobin *in vitro* and are assumed to do so as the result of conversion to some extremely active intermediate compounds. The ingestion of a toy-shaped deodorant

Table 31-1. Methemoglobinemia

I Acquired Methemoglobinemia, causative agents		
Type of Compound	Therapeutic Agents	Domestic and Industrial
A Nitrites and other direct oxidants	Amyl nitrite	Food adulterated with nitrites
	Sodium nitrite	Corning extract
	Nitroglycerin	Nitrous gases (arc welders)
	Bismuth subnitrate	Well water (nitrates)
	Ammonium nitrate	Food high in nitrates
	Silver nitrate (burns)	Potassium chlorate
	Quinones	Anilin dyes
B Indirect oxidants	Sulfonamides	Diaper marking ink
Aromatic amino	Sulfanilamide	Dyed blankets
and nitro compounds	Prontosil	Laundry marks

containing naphthalene and aniline<sup>3</sup> or red wax crayons containing p-nitroaniline<sup>31</sup>; contact with marking ink,<sup>18</sup> dyed blankets, or laundry marks on diapers; and benzocaine,<sup>19</sup> prilocaine,<sup>41</sup> resorcin, anilin dyes, or other aromatic compounds absorbed by mouth, rectally,<sup>22</sup> or percutaneously<sup>41</sup> have led to methemoglobinemia. Likewise, excessive exposure to such compounds industrially has been reported to produce methemoglobinemia.<sup>4</sup> Exposure to naphthalene was associated with methemoglobinemia in G6PD-deficient infants,<sup>16</sup> and malaria prophylaxis has been reported as provoking methemoglobinemia in unsuspected heterozygotes deficient in NADH-methemoglobin reductase.<sup>8</sup>

### Pathogenesis and Symptomatology

The rapidity of methemoglobin production depends on (1) the extent and rate of entry of the compound into the individual's circulation and into the erythrocytes; (2) the metabolism of the offending chemical compounds within the body; (3) the extent to which the compound is converted to intermediates with either increased or decreased oxidizing capacities; (4) the excretion of the compound; and (5) the rate at which the erythrocytes can reduce methemoglobin to hemoglobin. Thus, the effect of nitrite introduced intravenously is expended within an hour, while nitrobenzene does not produce its maximum effect for 12 to 15

hours.<sup>9</sup> The extent to which these factors are influential in different persons possibly may vary and this may explain why some seem to be more likely to develop methemoglobinemia or sulfhemoglobinemia than others.

Symptoms vary in intensity but are often mild. Concentrations of 10 to 25% methemoglobin produce cyanosis but are tolerated without apparent ill effects; at 35 to 40%, slight exertional dyspnea and headaches, as well as fatigue, tachycardia, and dizziness, may be experienced.<sup>5,14</sup> Lethargy and stupor may appear with concentrations of about 60%; the lethal concentration probably is greater than 70%.<sup>20</sup> Only rarely is enough methemoglobin present to cause death. Nevertheless, the mortality in infants fed formulas prepared with well water containing high concentrations of nitrate has been as high as 10%. Heinz bodies may be formed in the red corpuscles and hemolytic anemia may occur also. The high concentrations (50% or higher) have been observed in toxic methemoglobinemia but not in the hereditary forms.

The signs of toxicity in acquired methemoglobinemias have been noted to be greater than those produced by a corresponding degree of anemia. Consequently, some further action besides the lowering of the oxygen-carrying power of the blood has been suspected. It had been assumed that the toxic symptoms not accounted for by the lowered amount of available oxyhemoglobin were due to the effect of the methemoglobin-producing agent on the tissues. It was found, however, that a definite and reversible increase in oxygen affinity occurs, as in the presence of carboxyhemoglobin.<sup>13</sup> This means that in methemoglobinemia the tissues are subjected to anoxemia, not only from loss of the oxygen capacity of the blood, but also from increased difficulty in unloading from the blood such oxygen as is available. This effect has been attributed to the formation of compounds intermediate between reduced hemoglobin, in which all four iron atoms are ferrous, and methemoglobin, in which all are ferric. The conversion of one or more of the four ferrous atoms in the hemoglobin molecule to ferric

may lead to an increased affinity of the remaining ferrous atoms for oxygen.

### Treatment

No therapy other than prohibition of the offending chemical agent is needed if the methemoglobinemia is sufficiently mild, since reduction of the methemoglobin will occur as the result of the intact, normal reversion mechanism. If symptoms are sufficiently pronounced, methylene blue, 1 mg/kg body weight in a 1% solution, slowly given iv over a period of five minutes, is the agent of choice. In infants twice this dose is used. To patients of any age, if cyanosis has not disappeared within an hour, a second dose of 2 mg/kg body weight should be given. Dosages should not exceed 7 mg/kg since toxic effects such as dyspnea, precordial pain, restlessness and apprehension, a sense of oppression, fibrillar tremors, and even persisting cyanosis and hemolytic anemia<sup>15</sup> can develop. Methylene blue may also be given orally in doses of 3 to 5 mg/kg. Ascorbic acid has been administered orally in doses of 100 to 500 mg/day,<sup>2</sup> but methylene blue is more effective since it brings about reversion of methemoglobin by activating the pentose phosphate cycle (page 102) rather than by nonenzymatic reduction, a process which is slower than the normal system of cell conversion.

### Hereditary Methemoglobinemias

The hereditary forms of methemoglobinemia are much rarer than the acquired disorder. An enzymatic form and several varieties due to the inheritance of certain abnormal hemoglobins are recognized.

#### *NADH (DPNH)-Methemoglobin Reductase (Diaphorase) Deficiency*

Since this form of hereditary methemoglobinemia was specifically identified,<sup>103</sup> at least 100 patients have been shown to be affected.<sup>78</sup> Before a specific metabolic defect in the erythrocyte had been recognized, a

number of patients with hereditary methemoglobinemia in whom methemoglobinemia responded to the administration of methylene blue or ascorbic acid had been reported.<sup>60</sup> If these patients are assumed to have had the same illness, about 260 examples of proved or assumed DPNH-methemoglobin reductase deficiency can be cited.<sup>78</sup> Most cases have been in persons of European stock.<sup>52</sup> Reports of a high frequency in Navajos<sup>53</sup> and the earlier observations in Alaska<sup>72</sup> raised anthropologic questions of common origins, but inbreeding probably is a better explanation. Cases have been reported in Hindu, Chinese, North African, Cuban, and Puerto Rican families.<sup>20,76</sup> Investigations of erythrocytes from such patients have failed to reveal other consistent metabolic abnormalities.<sup>20,78</sup> In homozygotes the enzyme is completely lacking.<sup>21,103</sup> The absence of methemoglobin in heterozygotes is explained by the fact that the reducing capacity of red corpuscles is about 250 times the oxidizing activity.<sup>102</sup>

The characteristic clinical feature is the presence of cyanosis in contrast to the total lack or minimal character of other symptoms and signs. The patients are "more blue than sick." There is no clubbing of the fingers or evidence of cardiopulmonary disease. The contrast is especially striking if the cyanosis is pronounced. The hue may be slate-gray, gray-brown, or violet. It is generalized over the whole body but is particularly noticeable in the lips, the mucous membranes of the mouth, the tongue, the palate, the nose, over the cheekbones, on the ears, and at the extremities of the fingers and toes, especially under the nails. The cyanosis often has been present from birth.

Most of the methemoglobin is found within a minor population of red cells, presumably the aging ones and resulting from a decline in the activity of ancillary reduction pathways.<sup>84</sup> The decreased oxygen capacity which results from the presence of 20 to 50% methemoglobin in the blood of patients with long-standing untreated methemoglobinemia is sometimes associated with a mild compensatory erythrocytosis<sup>70,77,103</sup> but this is inconstant. The life span of the erythrocytes

is not altered, nor is that of the patients.<sup>20</sup> Severe mental retardation has been found in about 12% of children and young adults with NADH-methemoglobin reductase deficiency.<sup>78</sup> Reduced numbers of nerve elements and retarded myelination have been described in a few instances.<sup>77</sup> However, no really satisfactory explanation has been offered; the presence of another genetic or prenatal environmental abnormality seems possible.

Rapid screening tests for fast detection of red cell NADH-diaphorase deficiency have been described. One requires the addition of nitrated blood to a reaction mixture freshly prepared from stable stock reagents.<sup>83</sup> It is based on disappearance of fluorescence due to NADH, a principle used in the detection of various other red cell enzyme deficiencies (page 773). Another involves the brown color that forms on the addition of ferricyanide to blood and its failure to change to red when NADH is added, as occurs normally.<sup>99</sup> Assay of the NADH-methemoglobin reductase enzyme system in a hemolysate is required to confirm the diagnosis.<sup>17</sup>

Multiple aberrations in the NADH-methemoglobin reductase of human erythrocytes exist, some with and some without functional consequences.<sup>62</sup> Eight or more different electrophoretic variants have now been recognized.<sup>54,78,101</sup> One of these ("Boston Fast") appears to be associated with only a minimal decrease in activity, but significant methemoglobinemia was observed in association with five of them (Boston Slow, Duarte, Princeton, Puerto Rico, California).<sup>75</sup> Because of such observations, it has been postulated that this disorder is due simply to a deficiency of the enzyme or to the synthesis of an abnormal enzyme protein with reduced activity. The heterogeneous pattern of methemoglobin accumulation in vivo may arise from accelerated inactivation of variant NADH-methemoglobin reductase during the life span of the red cell.<sup>63,101</sup>

Treatment usually is not required, except for cosmetic reasons. Methylene blue, as described earlier (page 1013), may be used. Daily oral doses of 100 to 300 mg will usu-

ally maintain the concentration of methemoglobin at about 10% or less. Less efficacious is ascorbic acid, 500 mg daily by mouth.

### Other Metabolic Abnormalities Possibly Associated with Methemoglobinemia

Deficiency of NADPH (TPNH)-methemoglobin reductase has been described, but this defect was not associated with methemoglobinemia.<sup>100</sup> This would be expected since the reducing mechanism via the hexose monophosphate shunt is of much lesser importance than the glycolytic route. In a patient with 19% methemoglobinemia, inadequate synthesis of glutathione (GSH), inherited as a dominant trait, was thought to result in impaired glyceraldehyde-3-phosphate dehydrogenase activity and insufficient reduction of NAD to NADH, with consequent methemoglobinemia.<sup>112</sup> (See Fig. 3-14, page 103.) However, methemoglobinemia has not been found in patients with considerably less GSH in their erythrocytes.<sup>98</sup> Slight increases in methemoglobin have been reported in patients with hereditary hemolytic disorders associated with deficiencies in the activities of certain enzymes,<sup>87</sup> but none of these reports provides a basis for recognizing any significant forms of methemoglobinemia attributable to metabolic abnormalities of the erythrocyte other than NADH-methemoglobin reductase deficiency.

### Abnormal Hemoglobins Associated with Cyanosis

Altered heme function is associated with certain abnormal hemoglobins and this results in cyanosis. These are of three kinds: (1) hemoglobins that are unstable as the result of amino acid substitutions that affect their tertiary structure and alter hemoglobin linkage ("unstable hemoglobins, Chapter 24); (2) hemoglobins with reduced oxygen affinity (Hb Kansas, Hb Seattle, Table 24-1); and (3) the M hemoglobins, discussed below.

Hemoglobin M is rare but it is the most important hemoglobinopathy in Japan, where one form (Iwate) had been described originally as "hereditary nigremia," a condition

Table 31-2. Hemoglobin M Diseases

Hb M Boston <sup>1</sup> ( $\alpha_2^{58\text{Gyr}} \beta_2$ ) <sup>85</sup>

<sup>1</sup>Identical to Hb M Kiskunhalas,<sup>72</sup> Osaka,<sup>108</sup>

Gothenburg

<sup>†</sup>Identical to Hb M Kankakee,<sup>79,89</sup> Oldenburg<sup>98</sup>

<sup>‡</sup>Identical to Hb M Emory, Kurume,<sup>105</sup> Chicago,<sup>82</sup>

Radom<sup>71</sup>

<sup>§</sup>Identical to Hb M Akita<sup>107</sup>

characterized by blackish-brown blood.<sup>105</sup> Five different Hb M's have been distinguished according to the nature of the amino acid substitution in the  $\alpha$ - or the  $\beta$ -chains (Table 31-2).

The enzyme systems for reducing methemoglobin function normally in the erythrocytes of individuals with Hb M, but they are unable to reduce methemoglobin M to hemoglobin M. In four of the Hb M variants the distal ( $\alpha 58$ ,  $\beta 63$ ) or proximal ( $\alpha 87$ ,  $\beta 92$ ) histidine of the  $\alpha$ - or  $\beta$ -chain is replaced by tyrosine. Under such circumstances the ferric iron atom forms a stable bond with the phenolate side chains of the tyrosine molecule, the usual bond with histidine not being formed.<sup>98a</sup> The absence of the latter leads to slight alterations in the tertiary protein structure of the abnormal chain and stabilization of the quaternary structure, thereby lowering the oxygen affinity of the normal subunits.<sup>98a</sup> In Hb M<sub>Milwaukee-1</sub> the substitution of a glutamic acid for a valine in the heme pocket of the  $\beta$ -chains has been shown to lead to ionic linkage between the  $\gamma$ -carboxyl group of glutamic acid and the ferric iron.<sup>86,95</sup>

In addition to the M hemoglobins listed in Table 31-2, four have been reported which have not yet been fully characterized and therefore their significance is uncertain (Hb M<sub>Arhus</sub><sup>71</sup> Hb M<sub>Leipzig</sub><sup>54</sup> Hb M<sub>Milwaukee-2</sub><sup>97</sup> Hb M<sub>Reserve</sub><sup>91</sup>). Two M hemoglobins, Hb Sydney<sup>58</sup> and Hb Freiburg,<sup>80</sup> are unstable and were discussed in Chapter 24.

Cyanosis is usually the only clinical manifestation, but a shortened erythrocyte survival was reported in an individual with

Hb M<sub>Milwaukee-2</sub><sup>97</sup> and in one with Hb M<sub>Chicago</sub><sup>82</sup>, hemolytic anemia was reported in a patient with Hb M<sub>Akita</sub><sup>107</sup> as well as in the one with Hb M<sub>Freiburg</sub><sup>55</sup>. Inheritance, as with other hemoglobinopathies, is dominant. In the heterozygote the prognosis is good, but the homozygous state probably is incompatible with life. In those forms in which the abnormality is situated in the  $\beta$ -chain, cyanosis may appear only after a lapse of three or four months when the  $\gamma$ -chains have been replaced by the abnormal  $\beta$ -chains. It is inferred that the rate of synthesis of Hb M chains is lower than that of normal chains since, in most affected individuals, only 25 to 30% of the total hemoglobin is in the oxidized state. The methemoglobin seems to be present in all the red corpuscles.<sup>85</sup> Hb A is the other major component, except in Hb M<sub>Milwaukee-2</sub> which was found to be associated with Hb E.<sup>97</sup>

Hb M can be distinguished from other forms of methemoglobinemia by the spectroscopic examination of an acid methemoglobin hemolysate. Instead of the normal absorption maxima at 502 and 632 nm, wavelengths lower than 632 nm are found,<sup>66</sup> and there also are alterations in the spectrum between 500 and 600 nm which are distinctive for some of the variants.<sup>20</sup> Quantification is best accomplished, however, by electrophoresis at neutral pH after the hemolysate has been oxidized by potassium ferricyanide.<sup>64</sup>

## Sulfhemoglobinemia

Sulfhemoglobin, as mentioned earlier (page 1011), has not been completely characterized. It is unable to carry oxygen and, unlike methemoglobin, cannot be converted into hemoglobin.

Most of the oxidant drugs listed in Table 31-1 can convert hemoglobin to sulfhemoglobin, but the most common offenders are acetanilid<sup>117,125</sup> and phenacetin. Concentrations of sulfhemoglobin as high as 10 g/dl may be found without the life of the patient being endangered. Other than cyanosis, which may be very pronounced, few

or no symptoms can be attributed to the altered pigment. Since many of the patients who develop sulfhemoglobinemia are neurotic, their headaches and constipation, which are common complaints, probably cannot be attributed to the sulfhemoglobinemia. Symptoms of bromide intoxication from the ingestion of Bromo Seltzer often have complicated the clinical picture.<sup>117</sup> In some patients, increased red cell destruction, anemia, and Heinz bodies have been observed.<sup>118,123</sup>

Once formed there is no way of removing sulfhemoglobin except by venesection, which is unnecessary. Treatment consists of interdiction of the offending agent.

Why some patients develop methemoglobinemia and others sulfhemoglobinemia is unknown. Since sulfhemoglobinemia is relatively uncommon in spite of the widespread use of drugs such as phenacetin, some factor peculiar to the individual other than drugs may be required for its development. For a long time, constipation was assumed to provide hydrogen sulfide. As an alternative explanation the red corpuscle itself has been suggested as the source of hydrogen sulfide. In some of the patients the concentration of GSH in the erythrocytes has been elevated.<sup>119</sup> Only one case of congenital sulfhemoglobinemia has been reported.<sup>122</sup>

## Carboxyhemoglobin. CO Poisoning

Carboxyhemoglobin is produced by the combination of hemoglobin and carbon monoxide (CO). Hemoglobin in the form of carboxyhemoglobin (Hb CO) is unavailable for the carriage of oxygen. Hb CO is a dissociable compound, but the affinity of CO for hemoglobin is 218 times that of oxygen.<sup>145</sup> Consequently, if present in high enough concentration, CO is asphyxiating. On the other hand, if oxygen is provided, preferably 95% O<sub>2</sub>, 5% CO<sub>2</sub>, if necessary by positive pressure face mask, CO is displaced, the concentration being halved in 40 minutes under conditions of adequate ventilation.

Carbon monoxide is produced during

hemoglobin degradation and arises from the heme moiety.<sup>133</sup> Measurement of the endogenous production of <sup>14</sup>CO can be used to determine the life span of the red corpuscles (page 216).<sup>140</sup> Endogenous production of CO may be a hazard to infants in respirators and to men in submersibles and space capsules, and may add to the risk of closed-circuit anesthesia.<sup>136</sup> Almost any flame or combustion device emits CO; coal gas, water gas,<sup>142</sup> and the exhaust of automobiles are well-known sources.<sup>131</sup> CO is both colorless and odorless and its effects are insidious. In low concentrations in the inspired air (0.05% for one hour), resulting in a blood saturation of 20%, a mild or throbbing headache may develop. Longer exposure or higher concentrations, resulting in a blood saturation of 30 to 50%, cause headache, irritability, confusion, dizziness, visual disturbances, nausea, vomiting, and fainting on exertion. Exposure for one hour to concentrations of 0.1% in the inspired air results in blood saturations of 50 to 80% Hb CO with coma, convulsions, respiratory failure, and death. If the atmospheric concentration is sufficiently high, saturation of the blood proceeds so rapidly that unconsciousness may occur suddenly and without warning symptoms.

The most characteristic sign of CO poisoning is the cherry-red color of the skin and mucous membranes. This is due to the bright-red color of Hb CO.

The toxic effects of CO are solely the consequence of anoxia, but this may cause tissue changes such as edema, small hemorrhages, and perivascular infiltration with focal necroses. Consequently, although the administration of oxygen relieves the immediate ill effects of carbon monoxide inhalation, there may be a residue of permanent damage, especially to the central nervous system and the heart.<sup>136</sup>

## Detection of Abnormal Hemoglobin Pigments

If present in high enough concentrations, abnormal hemoglobin pigments can be de-

tected and the various types differentiated on gross examination of the blood. When they are present in lower concentrations, and for specific identification and quantitation, spectroscopic examination is necessary. In addition, appropriate studies should be made to demonstrate or rule out the presence of erythrocytosis, anemia, Heinz bodies (page 736), hemoglobinuria, and evidence of increased blood destruction (page 725). As discussed earlier (page 1016), starch block electrophoresis of hemolysates and spectrophotometric absorption analysis are required to establish a diagnosis of one of the Hb M disorders.

**GROSS EXAMINATION.** A sample of the blood, collected in a vessel containing an anticoagulant, should be centrifuged so that the plasma may be inspected for evidence of abnormal pigments and for hemolysis. The whole blood should also be inspected and then shaken in air for 15 minutes. Normally, the blood will become bright red as the reduced hemoglobin is converted to oxyhemoglobin. If it remains dark, abnormal intracellular pigments must be present. Blood containing methemoglobin is chocolate-brown. Sulfhemoglobin produces a mauve-lavender color. These colors are difficult to detect in whole blood, but, if dilutions of  $\frac{1}{100}$  or greater are made and the diluted blood is held against a white background, the colors are more easily differentiated. When carboxyhemoglobin is present, the blood is cherry-red. If there is uncertainty, 5 ml of 40% sodium hydroxide may be added to 5 ml of a 5% solution of blood in water. An oxyhemoglobin solution will turn brown, but a carboxyhemoglobin solution remains red.

**SPECTROSCOPIC AND OTHER METHODS OF EXAMINATION.** A hand spectroscope suffices if the concentration of the abnormal pigment is relatively high. If it is less than 10% or if quantitative measurements are required, it is necessary to resort to spectrophotometric<sup>24,152,169</sup> or colorimetric<sup>153</sup> and gasometric<sup>170</sup> procedures.<sup>185</sup>

The collection of the blood specimens

must be carried out with special care and should be prompt since, with the exception of sulfhemoglobin, the abnormal pigments disappear rapidly on removal of the causative agent or on institution of therapy. In obtaining the specimen, every precaution must be taken to prevent hemolysis. If hemoglobinemia is suspected, part of the blood should be allowed to clot. After allowing this portion to stand for an hour in the refrigerator, it is centrifuged without dislodging the clot. If carbon monoxide exposure is suspected, the blood should be collected in small tubes which are tightly stoppered, dry sodium citrate being used as an anticoagulant. For most other purposes, dry oxalate is preferable to heparin as an anticoagulant, but the latter is preferable if methemoglobin is suspected since oxalate increases the pH of the blood and favors the conversion of neutral methemoglobin to alkaline methemoglobin.<sup>165</sup>

In examining for methemoglobin and sulfhemoglobin, whole blood or washed red corpuscles are added to distilled water in a ratio of 1:10 or 1:100, depending upon the concentration of the abnormal pigment. A few ml of the hemolysed blood are placed in each of two test tubes. The first tube is then examined with the hand spectroscope. Methemoglobin produces a dark band at 630 nm in the red region of the spectrum (Plate XIII). To the second tube, 2 or 3 drops of 5% solution of potassium cyanide are added. If the pigment is methemoglobin, the band will disappear. Sulfhemoglobin produces a dark band at 620 nm which is difficult to distinguish from that of methemoglobin in the hand spectroscope, but it can be recognized by the fact that it is not removed by the addition of cyanide. Hydrogen peroxide (3%) causes both of these bands to disappear.

Spectrophotometry offers more precise as well as quantitative information. The essential principle<sup>151</sup> consists in the determination of the optical densities, at various wavelengths, of a dilute solution of hemolysed normal blood and repetition of the same procedure on the suspected sample. Details are given by Dubowski.<sup>152</sup>

## *The Porphyrrias*

Congenital Erythropoietic Porphyrria  
Acute Intermittent Porphyrria  
Variegate Porphyrria  
Hereditary Coproporphyrria  
Protoporphyrria  
Acquired Porphyrria

**T**HE porphyrias are a group of disorders characterized by the excessive production and excretion of porphyrins and porphyrin precursors. They result from hereditary or acquired defects in the pathways of heme biosynthesis (Chapter 4, page 169), and, for this reason, are often included within the discipline of hematology, even though abnormalities in the formed elements of the blood usually are absent or incidental.

At least six different kinds of porphyrias have been distinguished. These differ from one another clinically (Table 32-1) and in the type of porphyrin or pyrrole excreted (Fig. 32-1), the route of excretion, the major endogenous tissue source of the porphyrin or pyrrole, and the pattern of inheritance (Table 32-2).

### **Congenital Erythropoietic Porphyrria**

This rare inborn error of metabolism is characterized by the production in red cell precursors of porphyrins of isomer type I,

especially uroporphyrin I. Although probably first recognized by Schultz<sup>21</sup> and by Baumstark<sup>3</sup> in 1874, congenital erythropoietic porphyria was comprehensively described and distinguished from other porphyrias by Gunther in 1911.<sup>7</sup> It has been suggested that because their disease caused them to have red teeth and to be disfigured, hirsute, and nocturnal, persons with congenital erythropoietic porphyria may have been responsible for the werewolf legend.<sup>9</sup>

### **Genetics and Prevalence**

Congenital erythropoietic porphyria is inherited as an autosomal recessive trait and is by far the least common of the porphyrias, having been reported in only about 70 persons.<sup>17,20</sup> It occurs to a similar degree in males and females and has been described in a wide variety of racial groups, including English, French, Spanish, Italian, German, Polish and Norwegian Caucasians as well as Japanese and Indian Orientals and Bantus. Usually the illness is first detected in infancy and only rarely later in life.<sup>13</sup>

### **Clinical Description**

Often, the first sign of the disease is discoloration of the child's diapers by the urine, which ranges from pink to deep burgundy in color. The most prominent manifestation is pronounced cutaneous photosensitivity

Table 32-1. Major Clinical Manifestations of the Porphyrrias

Type of Porphyrin	Photosensitive Skin Lesions	Recurrent Acute Episodes*	Urine Appearance	Other Features
Congenital erythropoietic	Very severe	0	Red	Hemolytic anemia Erythrodontia
Acute intermittent	None	++	Darkens after standing	
Variegate	Moderately severe	+	Normal or red	
Coproporphyrria	Unusual	+	Normal or red	
Protoporphyrria	Mild	0	Normal	Biliary and hepatic disease
Acquired	Moderately severe	0	Red	Hepatic disease

\*Abdominal pain, peripheral neuropathy and mental symptoms often precipitated by drugs

(*hydraea aestivale*). Exposure to sun is followed by the development of vesicular or bullous lesions containing a porphyrin-rich fluid. The lesions tend to heal slowly, leaving pigmented scars. Often they become infected, ulcerated, and necrotic, leading, over a period of years, to progressive mutilation and disfigurement with loss of portions of the fingers, nose, eyelids, or ears (Fig. 32-2). Skin not exposed to light is unaffected. Often the patients adopt extreme precautions to avoid the sun.

Hypertrichosis is frequently present, usually manifested by downy, lanugo-like hair covering exposed parts of the body.<sup>16</sup> Deposition of porphyrin in the dentin of the teeth causes them to appear bright red (erythrodontia), brown, or yellowish. Even if discoloration is not apparent in ordinary light, the teeth may exhibit red fluorescence in ultraviolet light. If the ultraviolet light source is sufficiently intense, red fluorescence also may be seen in the phalangeal bones.
